In this paper we present observations of a substorm field-aligned current (FAC) system that DMSP F7 traversed just after 0300 UT on April 25, 1985. Ground magnetometer data show that a major substorm was in progress at that time and that DMSP F7 flew through a region of predominantly upward FAC. The DMSP F7 magnetic field data are consistent with this interpretation. The precipitating particle data suggest that there were three distinct large-scale FAC systems. In ascending latitude these were a downward current, an upward current, and a paired upward/downward current system. We identify the first current, which was coincident with the diffuse aurora, as region 2. The next (upward) FAC was coincident with a spatially unstructured region of energetic (~12 keV) electron precipitation. This was the substorm-associated FAC that made up part of the current wedge. The upward/downward current pair was coincident with a region of highly structured precipitation. We suggest that these currents may have been the duskside region 1 and, poleward of that, the extension of the dawnside region 1. The particle data show that the upward substorm current lay well equatorward of the boundary between open and closed field lines. In fact, using a model field, the equatorward boundary of the substorm FAC maps to the neutral sheet at $6.9 R_E$. While one should be cautious in stressing results obtained by mapping model field lines, our result is consistent with scenarios for substorms which postulate a disruption and diversion of the near-Earth cross-tail current.

INTRODUCTION

At substorm onset there is a reconfiguration of the magnetotail magnetic field toward a more dipolar orientation [McPherron *et al.*, 1973]. This reconfiguration is due to the reduction of a portion of the cross-tail current [Lui, 1978; Kaufmann, 1987]. The change in the cross-tail current has been interpreted in terms of the formation of a substorm current wedge [e.g., McPherron *et al.*, 1973] which diverts a portion of the current into the ionosphere via field-aligned currents (FACs), thereby reducing the equatorial current within a longitudinally limited sector. The current wedge closes in the ionosphere via the westward traveling surge (WTS) [Lühr and Buchert, 1988]. The WTS is composed of a western region of intense net upward FAC and a more diffuse region of net downward FAC to the east [Inhester *et al.*, 1981; Baumjohann *et al.*, 1981]. Upward FAC also flows from the Harang discontinuity [e.g., Kunkel *et al.*, 1986], which extends east of the WTS. This upward FAC is fed by the divergence of both eastward and westward electrojets. However, the bulk of the westward leg of the substorm current wedge corresponds to the upward current from the WTS.

The origin of the FACs which feed the substorm current wedge, and thus the WTS, is an important question which bears on the basic nature of substorms. The boundary layer model [e.g., Rostoker and Eastman, 1987] explicitly addresses this issue. That

model postulates that the WTS is composed of upward FACs associated with the Harang discontinuity flowing through the plasma sheet boundary layer (PSBL) and mapping to the distant tail. On the other hand, other models, such as the near-Earth neutral line model [e.g., McPherron *et al.*, 1973] and the current disruption model [e.g., Akasofu, 1972], suggest that the FACs which constitute the current wedge (and thus the WTS) have a relatively near-Earth origin. In this paper we will examine a case in which DMSP F7 flew through a FAC system during a substorm. Precipitating particle and magnetic field data from DMSP F7 and ground magnetometer data are available for this event. We will identify the substorm FAC portion of the current system and show that it was located well equatorward of the boundary between open and closed field lines. Moreover, we have mapped the equatorward boundary of the substorm FAC into the magnetotail using the Tsyganenko [1987] model, and we find that the boundary corresponds to $6.9 R_E$. This result is consistent with the idea that the region of substorm initiation lies relatively close to the Earth [e.g., Akasofu, 1972; Lopez and Lui, 1990] and that an essential feature of substorms is the disruption and diversion of the near-Earth current sheet.

OBSERVATIONS

We begin by presenting an overview of the observations. The event in question occurred during the early hours of April 25, 1985, and Figure 1 presents AE for that day. The previous day there had been an extended quiet period of several hours which began at 1900 UT. At ~0111 UT a small substorm occurred; that event has been studied in detail by Lopez *et al.* [1990]. A much larger substorm began just after 0200 UT. Figure 2 presents magnetogram data from Great Whale River (GWR; 67.4° , 356.6°). All ground station positions are given in PACE (Polar Anglo-American Conjugate Experiment) geomagnetic coordinates, described by Baker and Wing [1989]; the magnetograms were digitized with a

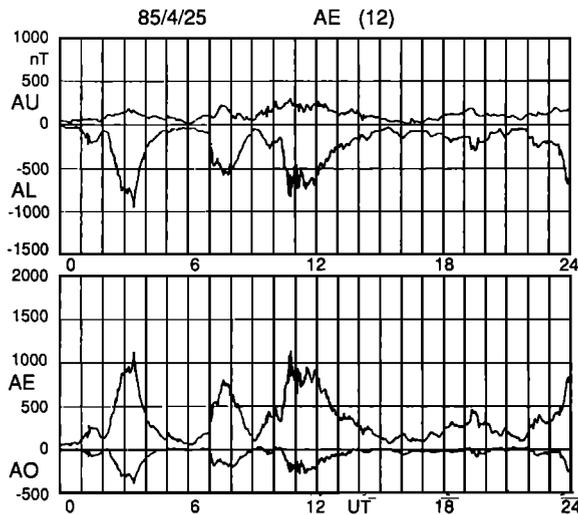

Fig. 1. AE for April 25, 1985. A period of strong substorm activity began just after 0200 UT.

1-min resolution. Given the extremely quiet magnetosphere prior to the active period [Lopez *et al.*, 1990], we may consider the values of the magnetic field at 0000 UT in Figure 2 to represent the background levels for those components. Significant substorm activity was recorded at GWR beginning after 0200 UT, and there were several distinct onsets, as evidenced by the repeated sudden H and Z variations and the positive D spikes. Churchill recorded similar variations (not shown), which indicates that the region affected by the substorm extended at least 2 hours to the west of GWR. The continuously negative Z component recorded after ~0230 UT indicates that the center of the westward electrojet remained poleward of GWR. Just before 0300 UT (when GWR was at 2202 MLT) a sharp negative Z , accompanied by a positive D perturbation, was observed. We associate these perturbations with one of the distinct onsets. Figure 3 presents mid-latitude magnetograms from Furstenfeldbruck (FUR; 42.54° , 87.45°) and Argentine Island (AI; -50.35° , 8.07°). We wish to focus on the interval beginning ~0245 UT, when both stations observed large positive H perturbations, a traditional indicator of substorm activity [e.g., Kokubun and McPherron, 1981]. In addition to the positive bays, both stations also recorded negative D perturbations. It is important

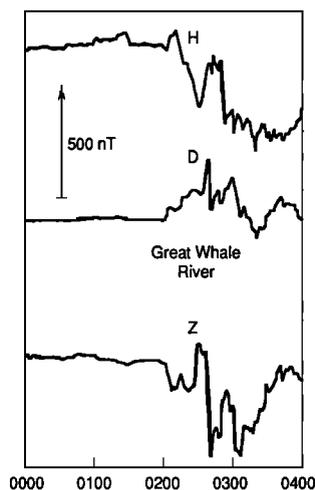

Fig. 2. Ground magnetometer data from Great Whale River.

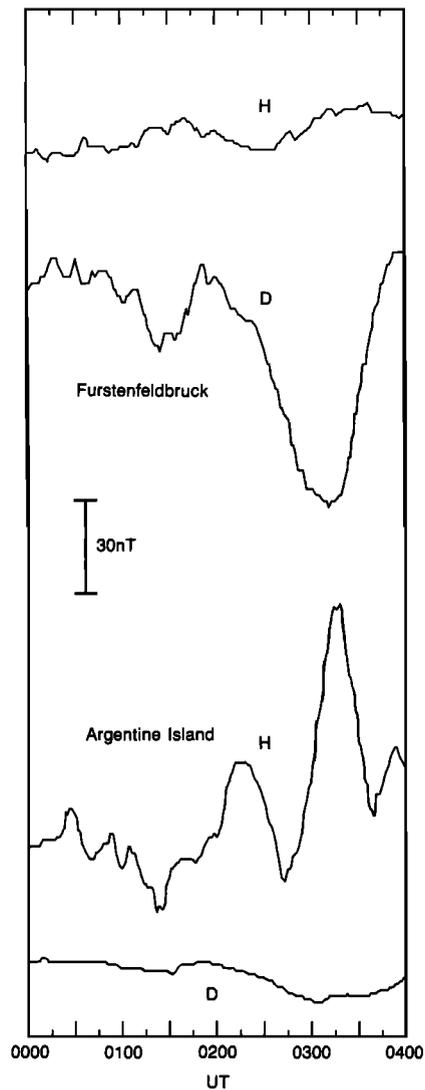

Fig. 3. Magnetograms from Furstenfeldbruck and Argentine Island.

to note (for purposes of interpreting the D perturbations) that the stations are in opposite hemispheres. One should also note that the D perturbation at AI was weak relative to the H perturbation, and vice versa at FUR.

DMSP F7 is a Sun-synchronous polar-orbiting satellite with an altitude of about 840 km, a period of 101.5 min, and an orbital plane approximately along the 1035–2235 local time meridian. Particle data (electrons and ions from 30 eV to 30 keV) and magnetic field data are available during the period of interest. A more detailed description of the DMSP spacecraft and the instrumentation is given by Hardy *et al.* [1984] and Gussenhoven *et al.* [1985]. Observations made by DMSP F7 of particle precipitation as the satellite passed over the southern polar region are presented in Plate 1 in spectrogram format; both ions (bottom panel) and electrons (top panel) are plotted. The lowest-energy ions (electrons) are at the top (bottom) of the panel, so that the lowest-energy particles of both species are at the center of the plot. The magnetic coordinates in the figure are PACE coordinates.

The particle data show an empty polar cap, a sharp poleward edge on the nightside, and a narrow dayside cusp; these features are indicative of southward interplanetary magnetic field B_z [Makita and Meng, 1984; Hardy *et al.*, 1986; Newell and Meng,

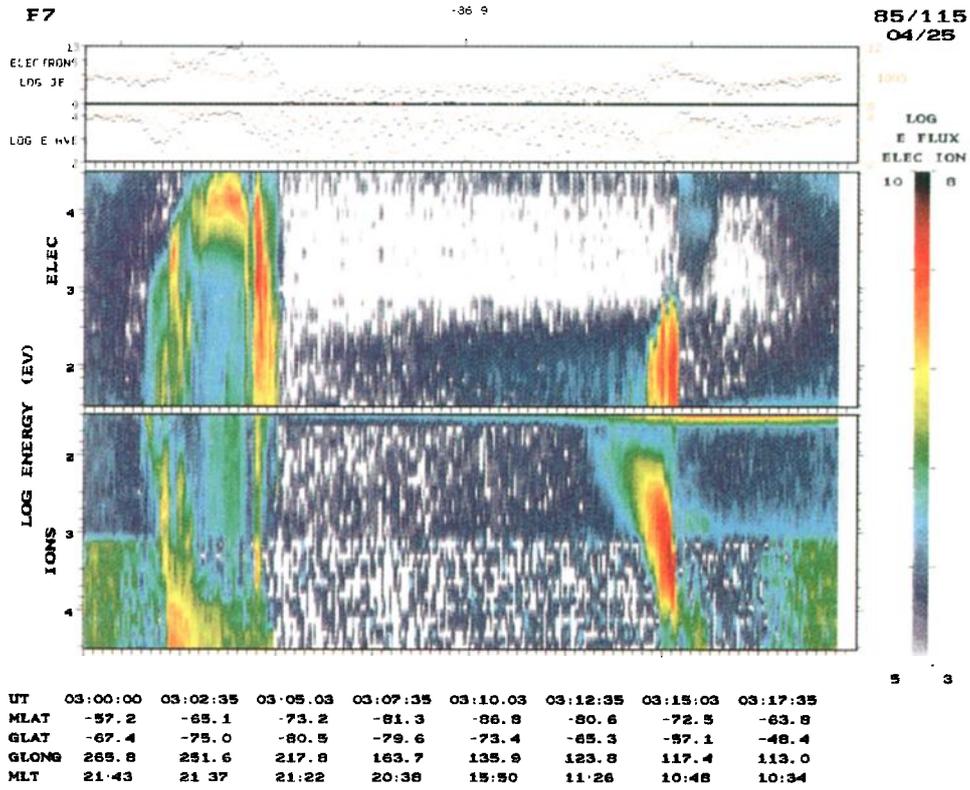

Plate 1. DMSP F7 ion and electron data during a polar cap pass on April 25, 1985. The data show a narrow cusp, an empty polar cap, and a sharp boundary between open and closed field lines.

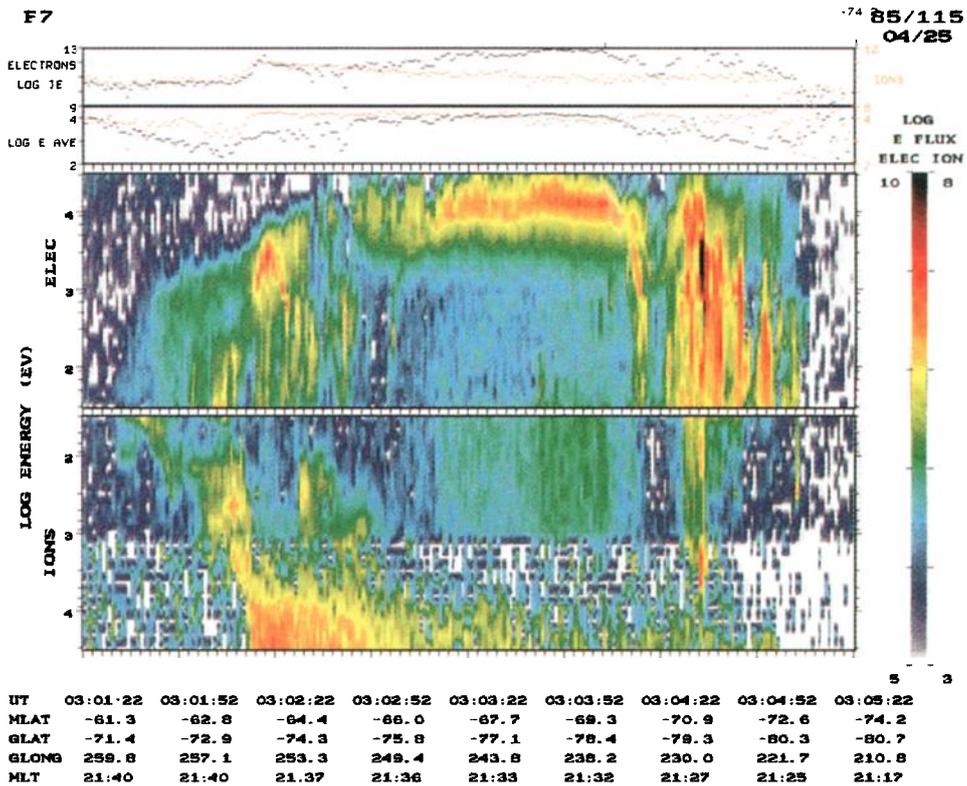

Plate 2. Four minutes of DMSP F7 particle data. The data show three distinct regions (from equatorward to poleward): (1) a region of diffuse precipitation (a small discrete arc was located within this region), (2) a broad, spatially unstructured region of energetic (12 keV) electron precipitation, and (3) a highly structured region whose poleward edge marks the boundary between open and closed field lines.

1987]. We have confirmed this by examining IMP 8 magnetic field data (not shown); although those data are only available beginning 0240 UT, they do show that B_z was southward with a magnitude of the order of 2.0 nT. The poleward boundary of the nightside precipitation marks the boundary between open and closed field lines. Plate 2 presents data from the same pass on the nightside, but at an expanded scale. At 0301:37 UT, DMSP F7 entered the diffuse aurora, which is characterized by spatially and spectrally unstructured precipitation [Feldstein and Galperin, 1985]. Imbedded within this region was a narrow discrete feature that the satellite encountered at 0302:12 UT. Following that, at ~0303 UT, DMSP F7 entered a broad and spatially (though not spectrally) unstructured region of precipitating energetic (~12 keV) electrons. Continuing poleward, there was a region of highly structured discrete precipitation that was quite different from the unstructured region both in spectral and spatial characteristics. Finally, the boundary between open and closed field lines (the poleward edge of the precipitation marking the boundary between plasma-filled and plasma-empty flux tubes) was encountered at -73.2° magnetic latitude (MLAT).

We would also like to mention two other points of interest relating to the particle data. First, the average energy of the ions shortly after 0302 UT increased as a function of geomagnetic latitude. This is in contrast to the statistical result of Hardy *et al.* [1989], which shows that the ion energy decreases with increasing latitude, and which was generally the case until just after 0302 UT. Thus the conditions observed were far from the statistical ones, suggesting that DMSP F7 detected freshly accelerated ions. Second, the DMSP F7 auroral image for this pass (not presented)

shows that the region of intense electron precipitation coincided with bright aurorae. However, the highly disturbed nature of the aurorae in the image makes unambiguous identification of any specific surge feature problematic.

Figure 4 presents the magnetic field deflections measured by DMSP F7 in two formats: a polar plot (which is a south polar projection from inside the Earth) and a line plot. The polar plot shows only those components perpendicular to the radial vector. The line plot shows all three components of the field, where ΔB_y is the component parallel to the satellite trajectory, ΔB_x is the radial component, and ΔB_z is the cross-track component; this component points essentially westward. Also indicated on the figure is the location of the conjugate point for GWR at 0300 UT. The data show a clear net eastward deflection of the magnetic field vector during the passage through the auroral zone as DMSP F7 moved poleward (north to south). This is consistent with a passage by the satellite through a net upward FAC sheet. It is important to note that the data come from the southern hemisphere and that the polar plot presents the perspective of an observer looking from a northern position down to the Earth, so that in that plot an upward FAC (i.e., negative ΔB_z) corresponds to a current going out of the back side of the figure.

The magnetic field deflection appears to have been composed of three major regions, each of which was coincident with a distinct precipitation region. The first region was marked by a slow westward deflection of the magnetic field which lasted until ~0303 UT; this was coincident with diffuse auroral precipitation. Superimposed on this deflection, just after 0302 UT, there was a small bipolar structure, the poleward part of which was coincident with

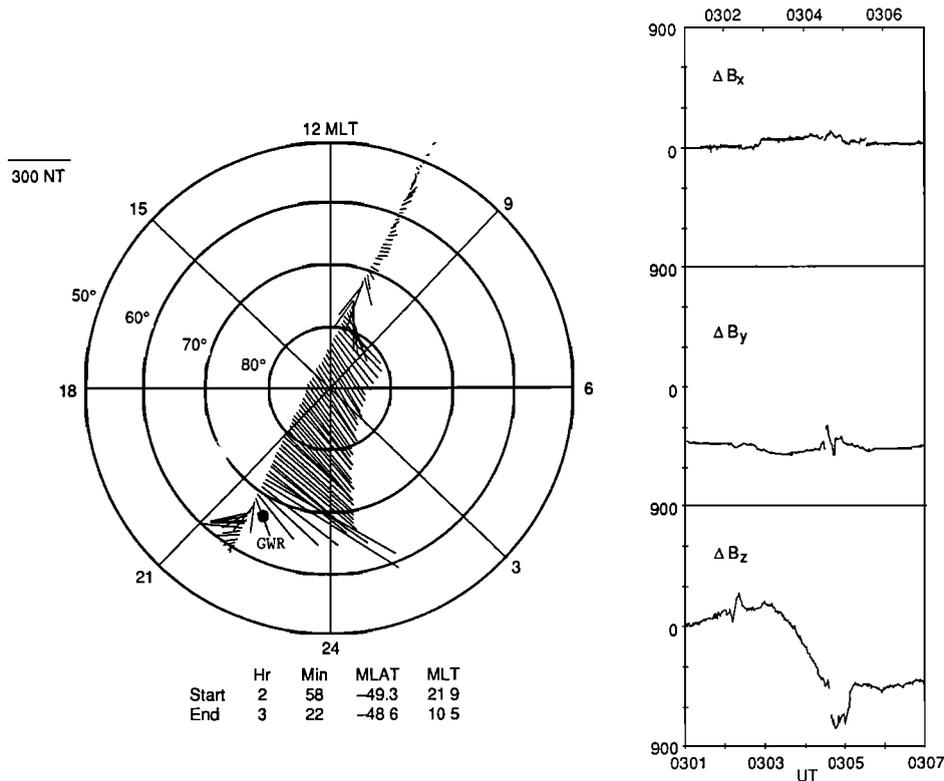

Fig. 4. Magnetometer data from DMSP F7 during a south polar pass. ΔB_x is the component parallel to the satellite trajectory, ΔB_y is radially inward, and ΔB_z is essentially westward. The data show a net eastward deflection of the magnetic field that we interpret as being due to a substorm-associated upward FAC. It is important to note that the polar plot is a south polar projection from inside the Earth, so an upward current in the polar plot corresponds to a current going out of the back of the figure. The conjugate point for GWR at 0300 UT is indicated by the dot.

the discrete particle feature observed at that time. The second region was characterized by a large eastward deflection that began at 0302:56 UT. The smooth variation in ΔB_z in this region was coincident with the spatially uniform 12-keV electron precipitation. This region ended at ~0304:20 UT, at which time DMSP F7 exited the uniform precipitation region. After the small precipitation gap seen in Plate 2, the slope of the ΔB decrease changed significantly. A minimum ΔB_z value was soon reached, ΔB_z oscillated near that value and then increased to a value roughly equal to the ΔB_z level at 0304:20 UT. This third region was coincident with the region of highly structured energetic electron precipitation. Also, it is important to note that the major part of the ΔB_z decrease was located poleward of the GWR conjugate point. Having presented an overview of the observations, we now proceed to examine their implications.

DISCUSSION

The AE data show that during the period in question, considerable substorm activity occurred, and this is reflected in the magnetograms discussed above. The sign of the D perturbation indicates whether a given mid-latitude station is east or west of the center of the substorm current wedge [e.g., Nagai, 1982]. Both Argentine Island and Furstenfeldbruck observed a negative D deflection, and since Argentine Island is in the southern hemisphere, the current wedge was centered between those two stations. We have confirmed this by examining other mid-latitude magnetograms (not shown) from San Juan, Fredericksburg, and Tucson. All those stations, which are west of AI, recorded positive D perturbations in association with the positive bay, which is expected when a northern hemisphere station is west of the center of the current wedge. Similarly, the station at Toledo, located between AI and FUR, recorded a negative D deflection (not shown). Moreover, the relative sizes of the D and H perturbations lead us to conclude that AI was near to and just west of the center of the current wedge.

The substorm was composed of multiple onsets, and the mid-latitude data show that an onset occurred at 0245 UT. It is that onset that we associate with the perturbations recorded at GWR from ~0245 UT onward. This includes the D spike at GWR that peaked at 0300 UT, which we interpret as being related to a surgelike feature, although we have no visual evidence that a surge moved over GWR at that time. The behavior of the H component also suggests that the western edge of a WTS passed directly over GWR [e.g., Akasofu *et al.*, 1966]. This implies that at 0300 UT, GWR was underneath a region of upward FAC [e.g., Samson and Rostoker, 1983], which is consistent with the mid-latitude observations.

The magnetic field observations made by DMSP F7 are consistent with southern hemisphere and heading poleward, an eastward deflection of the magnetic field can be interpreted as a net upward field-aligned current. As was pointed out above, the FAC system traversed by DMSP F7 appears to have been composed of three major regions. Assuming that the azimuthal deflections were caused by FACs, in increasing latitude those regions correspond to a downward FAC (with an upward/downward/upward structure imbedded within it), an upward FAC, and an upward/downward pair.

The most equatorward FAC was downward, and it was coincident with the diffuse aurora. We identify this current as region 2 because the sign and the latitudinal location of the current are consistent with region 2 and because region 2 has its origin in the near-Earth ring current [Iijima *et al.*, 1990]. Within the region 2 current was a small, discrete, precipitation structure; associated

with that structure was a bipolar magnetic perturbation. This suggests that discrete auroral arcs can map to the very near-Earth region that is the source of region 2.

The third current system was directed upward, and it was coincident with a broad region of unstructured precipitation; it was also responsible for most of the ΔB_z variation. We believe that this current was the substorm-associated FAC and that the region of precipitation corresponded to a portion of the WTS east of the westernmost edge but well within the region of intense upward FAC. This interpretation is consistent with the observations of GWR, which suggests that a surge moved over the station just minutes before DMSP F7 traversed the current system. The latitude of point conjugate to GWR would place that station within (but on the equatorward side of) the uniform precipitation region and the upward FAC, which is consistent with the negative Z observed at GWR. Our interpretation is also consistent with the result of Craven and Frank [1987]. They found that the substorm auroral brightening often begins at near 66° or 67° (magnetic latitude) and then expands primarily poleward. Furthermore, the spectral structure of the precipitation is typical of WTS precipitation, although the latitudinal extent of the feature is larger than one might expect (D. Gorney, personal communication, 1990). Since the aurora was probably expanding poleward [e.g., Craven and Frank, 1987], it is possible that some of the latitudinal extent was temporal in origin, rather than spatial. Also, the previous expansions may have been responsible for generating some of the observed precipitation region. Moreover, the DMSP F7 image (not presented) shows that the satellite passed through bright aurorae, lending further support to our interpretation. However, given that it is not possible in this case to unambiguously identify a specific surge in the image, our identification of the 12-keV electron precipitation and its associated upward FAC with a portion of a WTS should be considered tentative.

Another possible interpretation is that DMSP F7 traversed the Harang discontinuity, which is generally believed to be a source of upward FAC [e.g., Kunkel *et al.*, 1986]. The observations, however, suggest that this scenario is unlikely. The relatively large negative Z perturbation relative to the small negative H perturbation that occurred at 0300 UT suggests that GWR was located poleward of the center of the eastward electrojet and equatorward of the center of the westward electrojet. In that case, GWR was located very near the Harang discontinuity itself. Since GWR was in the northern hemisphere and DMSP F7 was in the southern hemisphere, one should ask "How well can we trust the conjugate point for GWR?" Wu *et al.* [1991] have recently addressed this issue, and they found that during the spring and fall, geomagnetic coordinate conjugacy holds rather well. We find additional support for that result in this case using the Trygvanenko [1987] model, which shows that the southern ionospheric footprint of the field line originating at GWR (at 110 km altitude) is located at $(-67.27^\circ, 357.62^\circ)$. Thus the conjugate point for GWR (see Figure 4) suggests that the bulk of the upward FAC that we call the substorm FAC was located poleward of GWR. The bulk of that FAC would have been drawn from the substorm-enhanced westward electrojet. Only a small portion at the equatorward edge of the westward electrojet might have been related to the upward FAC at the Harang discontinuity. However, any association between the equatorward portion of the upward FAC and the Harang discontinuity does not affect the conclusion that the upward current was a portion of the westward leg of the substorm current wedge.

The final current system was composed of two FACs of roughly equal magnitude. These FACs were coincident with the region of structured precipitation poleward of the broad upward FAC. That

region was quite different from the region equatorward of it, and it seems reasonable to suspect that these two currents were part of a system separate from the broad upward FAC. This is consistent with the fact that the currents were roughly of equal magnitude. *Iijima and Potemra [1976]* showed that the dawnside region 1 current (downward) extends into the premidnight sector poleward of the duskside region 1 current (upward). This corresponds to the observed pattern of currents in our case. Moreover, such quasi-permanent paired current sheets have been observed in the PSBL by *Nagai et al. [1990]*, and they are relatively independent of the substorm-associated currents. Therefore it is reasonable to postulate that this poleward system of roughly equal and oppositely directed current sheets may correspond to the quasi-permanent region 1 currents. The overall structure of the particle precipitation regions and their associated FACs is illustrated in Figure 5.

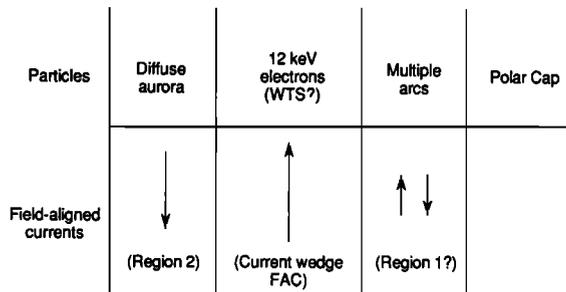

Fig. 5. Schematic illustration of the particle precipitation regions and their inferred field-aligned currents.

We may estimate the position of the source region in the magnetosphere of the substorm current using the magnetic field model of *Tsyganenko [1987]*. We find that the equatorward edge of the substorm FAC maps to a radial distance of $6.9 R_E$ and that the poleward edge of that FAC maps to $24.9 R_E$. Thus the near-Earth region would appear to have been the source of much of the substorm current that directly connects to the WTS. A similar conclusion was reached by *Lopez et al. [1990]*, who examined multipoint observations of the small substorm which occurred just after 0100 UT. We would like to point out that results obtained using a model field, especially during a substorm period, can be of questionable reliability. However, the mapping of the equatorward edge of the FAC cannot be greatly in error since at those distances from the Earth the dipole component is quite strong. In fact, SCATHA data (not shown) indicate that the near-midnight magnetic field at $R = 5.8 R_E$ was not extremely taillike at the time of the event.

Regardless of whether one believes the above mapping, it is important to note that both the substorm FAC and the upward region 1 FAC were located well equatorward of the boundary between open and closed field lines and that the main substorm current in that local time sector was upward. In fact, the open-closed boundary was located 6° poleward of the equatorward edge of the substorm-associated upward FAC. Given that the ionospheric projection of the PSBL is $\leq 1^\circ$ [*Dandouras et al., 1986*], the current must have been flowing through and connected to the central plasma sheet. Thus the observations appear to be consistent with substorm models which require the disruption and diversion of the cross-tail current sheet in the near-Earth region [e.g., *Akasofu, 1972; McPherron et al., 1973*], and are inconsistent with substorm models which locate the upward substorm currents in the PSBL.

CONCLUSION

On April 25, 1985, DMSP F7 flew through a field-aligned current system in the auroral region. Ground magnetic field data show that the local time sector traversed by DMSP F7 was located in the western part of the current wedge and that the net FAC was upward. The FAC system was composed of three major current systems. The most equatorward current was downward; it corresponds to region 2, and it was colocated with the diffuse aurora. The next current was upward, coincident with a region of spatially unstructured energetic electron precipitation, and it corresponds to the FAC in the substorm current wedge. We have tentatively identified this precipitation region and its attendant upward FAC with a portion of a westward traveling surge. The two other currents were of roughly equal magnitude and coincident with a region of highly structured precipitation. These currents may correspond to the region 1 current system. All upward FACs were located well equatorward of the boundary between open and closed field lines. Moreover, using the *Tsyganenko [1987]* model, we estimate that the equatorward edge of the substorm current system mapped to the neutral sheet at $6.9 R_E$ and the poleward edge mapped to the neutral sheet at $24.9 R_E$. The observations and model mapping are consistent with scenarios which place the region of substorm initiation in the near-Earth magnetotail and inconsistent with scenarios which place the region of substorm initiation in the distant tail.

Acknowledgments. We are pleased to acknowledge the aid of P. Newell, whose generous assistance was, as is often the case, invaluable. The DMSP F7 magnetic field data were graciously provided by F. Rich and the Geophysics Laboratory; the plots were produced by J. James, whose help is much appreciated. The ground magnetograms were provided by the World Data Center. We would also like to thank T. Lui, D. Sibeck, D. Gorney, and T. Rosenberg for several helpful conversations. Finally, we would like to thank one of the referees for bringing to our attention the point concerning the latitudinal dependence of the average ion energy, and the other referee for helpful detailed comments. The work performed at APL was supported by NASA under Task 1 of contract N00039-89-C-5301 and by NSF grant ATM-8713212. The work performed at The Aerospace Corporation was supported by the U.S. Air Force System Command's Space System Division under contract F04701-88-C-0089.

The Editor thanks J. S. Dandouras and another referee for their assistance in evaluating this paper.
