Abstract. A Lagrangian radiation fog model is applied to a fog event at Summit, Greenland. The model simulates the formation and dissipation of fog. Included in the model are detailed gas and aqueous phase chemistry, and deposition of chemical species with fog droplets. Model predictions of the gas phase concentrations of H_2O_2 , HCOOH , SO_2 , and HNO_3 as well as the fog fluxes of S(VI) , N(V) , H_2O_2 , and water are compared with measurements. The predicted fluxes of S(VI) , N(V) , H_2O_2 , and fog water generally agree with measured values. Model results show that heterogeneous SO_2 oxidation contributes to approximately 40% of the flux of S(VI) for the modeled fog event, with the other 60% coming from preexisting sulfate aerosol. The deposition of N(V) with fog includes contributions from HNO_3 and NO_2 initially present in the air mass. HNO_3 directly partitions into the aqueous phase to create N(V) , and NO_2 forms N(V) through reaction with OH and the nighttime chemistry set of reactions which involves N_2O_5 and water vapor. PAN contributes to N(V) by gas phase decomposition to NO_2 , and also by direct aqueous phase decomposition. The quantitative contributions from each path are uncertain since direct measurements of PAN and NO_2 are not available for the fog event. The relative contributions are discussed based on realistic ranges of atmospheric concentrations. Model results suggest that in addition to the aqueous phase partitioning of the initial HNO_3 present in the air mass, the gas phase decomposition of PAN and subsequent reactions of NO_2 with OH as well as nighttime nitrate chemistry may play significant roles in depositing N(V) with fog. If a quasi-liquid layer exists on snow crystals, it is possible that the reactions taking place in fog droplets also occur to some extent in clouds as well as at the snow surface.

Introduction

Ice cores recently retrieved at Summit, central Greenland, by groups from Europe (GRIP) and the United States (GISP2) potentially contain a record of atmospheric chemistry over approximately the last 250,000 years [Dansgaard *et al.*, 1993; Mayewski *et al.*, 1994]. The chemical composition of these ice cores includes species that originated as aerosols, as well as soluble gases. The main processes that deposit these species

onto the ice sheet are snow, fog, and dry deposition [Bergin *et al.*, 1994; Davidson *et al.*, 1996]. Recent work at Summit has shown that fog deposition of aerosol chemical species may contribute as much as one third to the chemical inventory in the summer snow layer and that deposition of soluble gases with fog may also be significant [Bergin *et al.*, 1995a, b; Dibb *et al.*, 1994].

The aerosol mass in summer at Summit is primarily dominated by sulfate (associated with various amounts of NH_4^+) with lesser contributions from chemical species including methanesulfonic acid (MSA), Na^+ , and Ca^{2+} [Bergin *et al.*, 1995b]. Important components of the atmospheric gaseous fraction which have been identified include the carboxylic acid formate (HCOOH), SO_2 , HNO_3 [Dibb *et al.*, 1994], NO_y (J.W. Munger, personal communication 1995), H_2O_2 [Bales *et al.*, 1995a, b], and HCHO (K. Fuhrer, personal communication 1995). All of these chemical species are involved in fog cycles either as condensation nuclei or as soluble gases dissolved in fog droplets. These chemical species are also reflected in ice core samples and used as potential tracers for sources and/or atmospheric processes in the reconstruction of past climatic conditions. If accurate estimates of past atmospheric concentrations of aerosols and soluble gases are to be made based on signals in the recently retrieved ice cores, it is important to better understand the relationship among fogs,

atmospheric chemistry, and the process of deposition of chemical species with fog in Greenland [Bergin *et al.*, 1995c]. It is particularly important to understand the extent to which fogs have influenced the chemical signals archived in ice cores.

Sulfate and nitrate are the dominant ionic species in ice core samples from Greenland and have both anthropogenic and natural sources [Mayewski *et al.*, 1990]. Based on several measurements made during the summer at Summit, Dibb *et al.* [1994] suggest that SO₂ concentrations are typically 20 ppt, with ratios of SO₂ to aerosol sulfate of approximately one third. H₂O₂ concentrations are typically around 1 ppb [Bales *et al.*, 1995], which suggests that aqueous phase oxidation of S(IV) to S(VI) by H₂O₂ may account for a significant fraction of the S(VI) deposition during fog. Measurements of gas phase nitrogen-containing species at Summit show that HNO₃ is typically less than 10% of the total NO_y. These measurements suggest that other nitrogen-containing species (such as PAN) may influence the deposition of N(V) with fog droplets via gas and/or aqueous phase reactions. This paper will address these issues and discuss the chemical processes that affect the deposition of N(V) and S(VI) with fog. In particular, we will focus on the following questions: (1) How does SO₂ influence the deposition of S(VI) with fog? (2) What role do the initial concentrations of HNO₃, NO₂, and PAN play in the deposition of N(V) with fog? In addition, we will study the detailed gas and aqueous phase chemistry associated with S(VI) and N(V) deposition with fog.

Depletion of atmospheric concentrations of aerosols and soluble gases and enhancement of the deposition of various chemical species with fog has previously been shown for areas such as Southern California [Pandis and Seinfeld, 1989a; Munger *et al.*, 1990] and the Po valley [Fuzzi *et al.*, 1988; Noone *et al.*, 1992]. These studies have shown that complex chemistry takes place in fog droplets and is responsible for the production and redistribution of chemical species between gases and aerosols.

Summit, Greenland, provides a unique opportunity to study fog formation and chemistry. Several experiments have been performed during the last several years as part of the GISP2 atmospheric sampling program (ATM) [Jaffredo *et al.*, 1995; Dibb *et al.*, 1996] that include measurements of parameters related to the deposition of chemical species with fog, such as micrometeorological parameters, gas and aerosol concentrations, and fog droplet chemistry. The data serve as inputs and verification for the fog model presented in this paper. The modeling of fogs at Summit is simplified since the location is essentially flat with as many as 17 radiative fogs occurring in a summer month, typically lasting for several hours. The wind speeds during these fogs are relatively low (< 3 m/s) and the mixing with air aloft is generally restricted. The fluxes from the surface snow are apparently minor during fog events for many of the chemical species which simplifies the modeling of fogs since emission inventories are not needed [Bergin *et al.*, 1994].

In this paper the fog model of Pandis and Seinfeld [1989a] is modified for conditions at Summit. The model is used to

better understand the relationship between the concentrations of gas and aerosol chemical species and the deposition of these species with fog at Summit. The model is also used to interpret measurements of soluble gas phase chemical species. In particular, the model gives insight into the effects of local meteorology, aqueous phase solubility of gases, and gas and aqueous phase chemistry on the deposition of chemical species with fog, as well as gas and aqueous phase reactions affecting fog droplet chemistry, which may also occur in the quasi-liquid layer of snow crystals.

First, the model is presented with a brief description of important parameterizations and boundary conditions. Next, model results are compared with soluble gas phase concentration measurements made during a fog event. Following this, predicted fluxes of chemical species with fog are compared with measurements. Next, the effect of SO₂ on the deposition of S(VI) is discussed. After this, the gas and aqueous phase chemistry influencing the deposition of N(V) with fog is discussed. Next, the sensitivity of the model to various input parameters is presented. Finally, the impact of the model results on the interpretation of past atmospheric chemistry based on ice core chemical signals is discussed.

Model Description

Fog Module

A one-dimensional Lagrangian trajectory model is used to simulate the development, growth, and dissipation of fog. The model consists of three submodels for the formation and dissipation of fog, gas phase chemistry, and aqueous phase chemistry, which estimate the time-resolved vertical profiles of temperature, relative humidity, and liquid water content as well as gas and aqueous phase chemical species.

The governing equations for the radiation fog model are the one-dimensional continuity equations for energy in the air (equation (1)) and snow (equation (2)) as well as for water vapor (equation (3)) and liquid water (equation (4)) in the air [Pandis and Seinfeld, 1989a]:

$$\frac{\partial T}{\partial t} = -\frac{1}{\rho c_p} \frac{\partial F_r}{\partial z} + \frac{\partial}{\partial z} \left[K_h \left(\frac{\partial T}{\partial z} + \Gamma \right) \right] + \frac{L}{\rho c_p} C \quad (1)$$

$$\frac{\partial T_s}{\partial t} = K_s \frac{\partial^2 T_s}{\partial z^2} \quad (2)$$

$$\frac{\partial q}{\partial t} = \frac{\partial}{\partial z} \left(K_q \frac{\partial q}{\partial z} \right) - C \quad (3)$$

$$\frac{\partial w}{\partial t} = \frac{\partial}{\partial z} \left(K_w \frac{\partial w}{\partial z} \right) + \frac{\partial G}{\partial z} + C \quad (4)$$

where T is the air temperature (K), ρ the density of air (g/m³), F_r the net radiation flux (W/m²), Γ the adiabatic lapse rate

(K/m), c_p the specific heat of air (J/g K), L the latent heat of vaporization of water (J/g water), C the water condensation rate (g/m³ s), T_s the snow temperature (K), q the water vapor concentration (g/m³), w the liquid water concentration (g/m³), G the liquid water gravitational flux (g/m² s), K_h , K_q , and K_w the exchange coefficients for heat, water vapor, and liquid water (m²/s), and K_s the thermal conductivity of snow (W/m).

The system of partial differential equations is solved for 65 grid cells of varied size starting at 1 m below the snow surface and up to 400 m above the snow surface. Equations (1), (3), and (4) are solved from the ground surface to 400 m, while equation (2) is solved from the surface to 1 m below the snow surface. Thirteen variable size grid cells are used inside the snow and 52 in the atmosphere.

The radiation flux, F_r , is calculated using the radiation model of *Zdunkowski et al.* [1982]. The radiation scheme accounts for the effects of gases, particles, clouds, and fog droplets on the radiation flux. The radiation grid contains 74 cells extending from the ground to 50 km.

The exchange coefficients for heat, liquid water, and water vapor are assumed to be equal [*Brown and Roach*, 1976]. The atmospheric stability-dependent exchange coefficients are estimated on the basis of surface roughness, wind speed, and temperature profile [*Shir*, 1973]. We assume that the thermal conductivity of snow is 0.52 W/m K [*Albert and McGilvery*, 1992] and constant with snow depth.

The condensation rate, C , is evaluated at each model time step in the case that a cell is saturated with respect to water vapor. In this case, all of the water vapor above the saturation value is assumed to condense in the liquid phase. The temperature in the cell is then corrected for latent heat effects as described by *McDonald* [1963].

To estimate the gravitational fluxes of fog droplets, it is necessary to know the droplet settling velocity. The relationship between the gravitational flux, G , and the fog droplet settling velocity, u_{av} , can be parameterized as

$$G = w u_{av} \quad (5)$$

The fog droplet settling velocity, u_{av} , is parameterized as follows [*Brown and Roach*, 1976]:

$$u_{av} = a_g w \quad (6)$$

A limited number of measurements of fog droplet size distributions were made using an FSSP probe during the 1991 field season at Summit and indicate that the mass mean diameter of fog droplets is approximately 20 μ m [*Borys et al.*, 1992]. Using these data, a_g has a mean of 0.20 m⁴/g s. The estimates are made by using equation (6) with the mean liquid water content for the measurements along with estimates of u_{av} based on Stokes law [*Pandis and Seinfeld*, 1989a]. The mean a_g value at Summit is within the range of values reported by *Pandis and Seinfeld* [1989a].

Boundary Conditions

The temperature and water vapor concentration is assumed to be constant at the top of the model domain (400 m) as well

as at 1 m below the snow surface. The flux of liquid water across the upper boundary is considered to be zero. At the ground surface the temperature of the air and snow are considered to be equal. The condition for the net heat flux at the air/snow interface is used to couple the energy balance in the air and snow and can be written as

$$-F_r + F_H + F_L - F_S = 0 \quad (7)$$

where F_r is the net longwave and shortwave radiative flux, F_H and F_S are the sensible heat fluxes through the air and snow, and F_L is the latent heat flux. We assume that a quasi-liquid layer exists on the surface of snow crystals [*Conklin and Bales*, 1993], and the water vapor concentration in the lowest cell is estimated using the method proposed by *Turton and Brown* [1987], which considers the saturation vapor pressure at the surface as well as the surface resistance to evaporation of water vapor.

The set of partial differential equations are solved using the Crank-Nicholson method with a 1-s time step. For this time step no instabilities occur in the model. A detailed explanation of the fog model is given by *Pandis and Seinfeld* [1989a].

Gas and Aqueous Phase Chemistry Modules

The gas phase chemistry mechanism for the SO₂/NO_x/hydrocarbon system includes 154 reactions with 62 species [*Carter and Atkinson*, 1988]. The aqueous phase mechanism is from *Pandis and Seinfeld* [1989b] and contains 49 aqueous phase species, 20 gas-phase aqueous-phase reversible reactions, and 109 aqueous phase reactions. Transport of species between the gas and the aqueous phases is calculated explicitly using the method described by *Pandis and Seinfeld* [1989b]. The accommodation coefficients (a_w) for gaseous species onto fog droplets is assumed to be 0.01 in the base case simulations [*Pandis and Seinfeld*, 1989b]. The sensitivity of the model to this parameter will be explored below.

General Model Description

The computational domain for gas and aqueous phase chemistry is divided into nine cells in the lower 400 m of the atmosphere, where fog is expected, with three additional cells from 400 m to 1000 m. *Bergin et al.* [1994] report that during fog events the dry deposition of aerosols and soluble gases is negligible compared to the flux of these chemical species with fog. Therefore we assume that dry deposition of aerosols and gases during the fog event has a negligible effect on the net fluxes of chemical species (i.e., the dry deposition velocities are assumed to be zero for all of the chemical species). The vertical transport of gases and aerosols is solved using the approach of *McRae et al.* [1982].

The fog submodel supplies vertical profiles of the liquid water content to the main model. The main model simulates the aqueous phase chemistry, vertical transport of chemical species with fog, and deposition of species with fog to the snow surface. The model assumes that when fog forms in a cell, all of the aerosol mass is scavenged by fog droplets. This

Table 1. Aerosol and Gas Model Input Concentrations

Atmospheric Concentration		Source	Comment
<i>Aerosols, ng/m³</i>			
SO ₄ ²⁻	340	<i>Bergin et al.</i> [1995b]	1993 summer, measurements at Summit
NH ₄ ⁺	40	<i>Bergin et al.</i> [1995b]	1993 summer, measurements at Summit
<i>Gases, ppb</i>			
HNO ₃ *	0.054	<i>Dibb et al.</i> [1994]	1993 summer, measurements at Summit
NO _x	0.030	<i>Sandholm et al.</i> [1992]	1988 summer, Arctic free troposphere
SO ₂	0.029	<i>Dibb et al.</i> [1994]	1993 summer, measurements at Summit
HCOOH	1.62	<i>Dibb et al.</i> [1994]	1993 summer, measurements at Summit
H ₂ O ₂	1.52	<i>Bales et al.</i> [1995b]	1993 summer, measurements at Summit
HCHO	0.50	Fuhrer, communication, 1995	1994 summer, measurements at Summit
PAN	0.54	Munger, communication, 1995	1994 summer, measurements at Summit

generally agrees with impactor data in and out of fogs, which suggest that typically all of the coarse mode aerosol mass and at least 70% of the accumulation mode aerosol mass serve as condensation nuclei during fog formation [Bergin *et al.*, 1995b].

Measured Parameters

Input Data

The fog model is applied to a fog event at Summit, Greenland which began on June 21, 1993, at 2000 and lasted until 0600 the following morning. The simulation starts at 1800 on June 21 and ends at 1400 on June 22.

The initial atmospheric temperature profile (at 1800 on June 21) is taken from a tethered flight which recorded the temperature, pressure, and wind speed profiles in the lower 500 m of the atmosphere [Bales *et al.*, 1995b]. Since accurate relative humidity profile measurements are not available, the initial relative humidity is assumed to be constant at 88% for the 400 m profile at Summit. The sensitivity of the model to this assumption will be investigated below. The initial temperature profile in the snow is assumed to linearly decrease from the snow surface to a value of 254 K at 1 m below the surface. This value is based on snow pit temperature profile measurements made at 1800 on June 21. The hourly averaged wind speeds used in the model are from a meteorological station at Summit. For most of the fog event the wind speed is approximately 2 m/s and increases to 5 m/s after 0600 on June 22.

The initial aerosol and gas phase concentrations are given in Table 1. The input concentrations for the aerosol chemical species SO₄²⁻ and NH₄⁺ are taken from filter samples collected at the atmospheric camp (ATM) located 10 km SSW of the GISP2 main camp [Bergin *et al.*, 1995b]. The gas phase

concentrations of HNO₃*, SO₂, and HCOOH are from mist chamber samples obtained at the GISP2 main camp reported by Dibb *et al.* [1994]. It is worthwhile to point out that the nitric acid concentration estimated from NO₃⁻ in mist chamber samples is denoted as HNO₃*. This is because NO₃⁻ measurements in mist chamber samples may contain contributions from other species such as PAN and organic nitrates (RONO₂), in addition to HNO₃ [Dibb, 1996]. This point will be discussed in the section on HNO₃. H₂O₂ gas phase concentrations are from measurements conducted at the GISP2 main camp and are reported by Bales *et al.* [1995a, b]. Although HCHO measurements are not reported for the 1993 field season, values are assumed to be similar to the mean value measured during the 1994 field season at Summit (K. Fuhrer, personal communication 1995). Similarly, direct measurements of PAN have not been made at Summit and the initial PAN concentration is based on NO_y measurements made during the 1994 field season, which suggest that HNO₃ is typically less than 10% of the total atmospheric NO_y (J.W. Munger, personal communication 1995). The NO_y values measured during the 1994 field season ranged from 0.3 ppb to 5 ppb. We therefore assume that a large fraction of the NO_y at Summit is PAN and approximate the initial PAN concentration as 10 times the initial HNO₃* concentration. Since NO_x measurements have not been made at Summit, the concentrations of NO and NO₂ are assumed to be 10 ppt and 20 ppt, respectively. These values are based on measurements made in the Arctic free troposphere during the ABLE 3A missions [Sandholm, 1992]. The concentrations of CH₄ and CO are assumed to be their global background values of 1.7 ppm and 75 ppb, respectively [Thompson *et al.*, 1993].

Both aerosol and gas phase measurements were made at ground level (1.5 m). Since vertical profiles of aerosols and gases have not been measured, we assume that the initial

Figure 1. (a) Measured initial atmospheric temperature profile on June 21 at 1815 (used as model initial condition) and (b) observed versus predicted temperature profile on June 22 at 0000.

concentration profiles are uniform with the same values as the concentrations measured at ground level.

Fog Chemical Fluxes

Fluxes of several chemical species for the fog event occurring at 1800 on June 21 and ending at 0600 on June 22 were measured by Bergin *et al.* [1995b]. Fog samples were analyzed for SO_4^{2-} and NO_3^- by ion chromatography (IC) [Bergin *et al.*, 1995b] and for H_2O_2 [Bales *et al.*, 1995]. The fluxes of the chemical species are estimated by multiplying the concentrations by the mass of fog deposited per area. The fluxes of the chemical species estimated between replicate samples are within 10%.

Model Results and Discussion

Fog Development

The model predicts that the fog begins at 2000 and dissipates the following morning at 0600, in agreement with field observations. Figure 1a shows the atmospheric temperature profile on June 21 at 1815, which serves as an initial condition for the atmospheric energy balance (equation (1)). The observed and predicted temperature profiles on June

22 at 0000, several hours into the fog event, are depicted in Figure 1b. It is worthwhile to point out that the model accurately reproduces the 10°K cooling observed at the ground level as well as the cooling in the bottom 100 m of the atmosphere. This suggests that the model correctly estimates the eddy diffusivity, which is a function of several parameters including the atmospheric stability, wind speed, and surface roughness. This parameter is crucial in correctly estimating the fluxes of heat as well as gas phase species. Also, the heat flux boundary condition (equation (7)) that couples the air and snow compartments appears adequate.

Figure 2a shows the predicted liquid water content (LWC) in the lowest model cell during the fog event. The mean LWC in the bottom cell for the fog event is 0.075 g/m^3 . Although measurements of the LWC were not made during the 1993 field season, LWC measurements in similar fog events during the 1991 field season ranged from 0.03 g/m^3 to 0.30 g/m^3 [Borys *et al.*, 1992], in general agreement with the LWC predicted in Figure 2a. The cumulative flux of fog water to the surface is shown in Figure 2b. From 2300 on June 21 to 0200 on June 22 the cumulative flux curve is linear, which suggests the fog droplet flux to the surface is constant during this time period. This is due to the relatively constant LWC in the lowest cell during this time period, which determines the water flux. For the last 3 hours of the fog event the cumulative flux levels off, which is due to the significant decrease in the LWC as the fog dissipates. The predicted evolution of the LWC vertical profile during the fog event is given in Figure 2c. The fog builds to a height of 140 m on June 22 at 0400, at which time the mean vertical liquid water content is 0.07 g/m^3 . The atmospheric temperature begins to increase due to radiative heating of the ground and the conduction of heat from deeper snow to the snow surface and the fog completely dissipates on June 22 at 0600.

Gas Phase Concentrations During Fog

Hydrogen peroxide (H_2O_2). Figure 3a shows predicted and observed gas phase concentrations of H_2O_2 in the ground cell during fog. H_2O_2 can react with SO_2 dissolved in cloud and fog water to produce SO_4^{2-} [Daum *et al.*, 1983; Pandis and Seinfeld, 1989b] and therefore enhances the deposition of S(VI) with fog. The model results generally agree with measured values, although the model appears to underestimate the H_2O_2 concentration during the fog event. The model results suggest that all of the H_2O_2 enters the aqueous phase, while the measurements show that approximately 20% of the initially present H_2O_2 remains in the gas phase. If the measured gas phase value of 0.4 ppb during the fog event is considered an equilibrium value, then Henry's law predicts that the fog water concentration should be $720\text{ }\mu\text{M}$. The measured fog water H_2O_2 concentration is only $50\text{ }\mu\text{M}$, more than an order of magnitude lower than the equilibrium estimation. This suggests that either the measurement technique is biased or that equilibrium is not reached in the timescale of the fog. Measurements by Noone *et al.* [1991] have suggested that H_2O_2 is apparently close to Henry's law equilibrium in ambient clouds. The estimated timescale for equilibrium should be of the order of several

minutes, and therefore the latter explanation is not satisfactory. The difference in measured and predicted gas phase concentrations may be due to the sampling of fog droplets by the instrument, which would result in an overestimation of the atmospheric H_2O_2 concentration (M. Losleben, personal communication 1995) although this cannot

be quantitatively verified. It is not likely that entrainment from higher concentration air above the fog region affects surface concentrations during the fog event, since the atmosphere in the fog region is extremely stable. Gill *et al.* [1983] suggest that organic compounds may coat the surface of droplets, affecting the mass transport of gases between the gas and the aqueous phases. Winiwater *et al.* [1994] also suggest that the presence of organic surface coatings may affect mass transport to droplets. Unfortunately, there is not a great deal of information available on the effect of droplet surface coatings on mass transport, and experiments performed at Summit do not allow the existence of such surface coatings to be substantiated. The effect of a surface coating can be parameterized by decreasing the droplet accommodation coefficient and will be discussed below. H_2O_2 is relatively soluble in fog water and Figure 3a shows that the gas phase H_2O_2 concentration significantly decreases within the first few hours of fog. During the fog event, H_2O_2 is lost due to scavenging by fog droplets and deposition to the ground. After the fog event the H_2O_2 concentration gradually increases due to mixing with higher concentration air from aloft, which was above the fog layer during the fog event.

Formic acid (HCOOH). Figure 3b shows the predicted and observed gas phase concentrations of formic acid (HCOOH). Both the model results and the measurements are in general agreement and show that HCOOH concentrations decrease during the fog event. However, a significant fraction of HCOOH remains in the gas phase, which is expected for this moderately soluble species [Pandis and Seinfeld, 1989b; Dibb *et al.*, 1994]. At about 0400 the fog begins to dissipate and the concentration gradually increases due to mixing with air aloft, until about 0700. After this time the concentration of HCOOH gradually decreases until the end of the simulation. This is due to the gas phase destruction of HCOOH by reaction with OH [Carter and Atkinson, 1988].

Sulfur dioxide (SO_2). Figure 3c shows predicted and observed SO_2 concentrations during fog. The model predicts that essentially all of the SO_2 is transferred from the gas phase to the aqueous phase within the first several hours of the fog. In the aqueous phase S(IV) reacts with H_2O_2 to produce S(VI) , which will be discussed in more detail below. Although the uncertainties in the gas phase SO_2 measurements are quite high, the model results apparently underpredict the SO_2 concentrations during fog. Because of the low wind speeds and stable atmospheric conditions during fog, it is not likely that significant transport of SO_2 from above the fog model spatial domain (400 m) occurred. It is also not likely that local contamination from the GISP2 camp contributed to SO_2 concentrations, since the camp was 1 km downwind of the sample sight for the duration of the measurements. It is likely that the mist chamber measurements are very close to the detection limit and the discrepancy between the model results and the measurements may be due to the accuracy of the mist chamber technique under the particular sampling conditions at Summit.

Nitric acid (HNO_3). NO_3^- is the dominant ionic species in ice core samples and includes contributions from

Figure 2. (a) Liquid water content (LWC) in the lowest cell during fog (b) cumulative water flux during the fog event, and (c) LWC profile for 3 times during the fog event.

Figure 3. Predicted and observed atmospheric gas phase concentrations of (a) H_2O_2 , (b) formic acid (HCOOH), (c) SO_2

and (d) HNO_3^* (case 1 is $\text{HNO}_{3,i}=0.054$ ppb, $\text{NO}_y^*=0.000$ ppb; case 2 is $\text{HNO}_{3,i}=0.024$ ppb, $\text{NO}_y^*=0.030$ ppb).

anthropogenic and natural sources [Silvente and Legrand, 1995]. As previously discussed, NO_3^- collected in mist chamber samples may originate from HNO_3 vapor as well as from other NO_y species such as PAN, RONO_2 , or other organic nitrates [Sandholm et al., 1992] here written as NO_y^* . Measurements of PAN and RONO_2 species reported for early spring at Alert suggest that PAN concentrations are typically 10 times greater than RONO_2 concentrations [Muthuramu et al., 1995]. Measurements carried out during the Arctic Boundary Layer Expedition (ABLE 3A) also indicate that RONO_2 concentrations are less than 10% of PAN concentrations [Singh et al., 1992]. It is likely that the majority of the NO_y at Summit is PAN, although the existence of other organic nitrates cannot be ruled out. Therefore HNO_3 values estimated from NO_3^- in mist chamber samples (HNO_3^*) are likely overestimates of the actual gas phase HNO_3 concentrations, and the HNO_3^* concentration can be written as

$$\text{HNO}_3^* = \text{HNO}_3 + \text{NO}_y^* \quad (8)$$

Figure 3d shows HNO_3^* concentrations for two model runs along with measured values. Two hypotheses are tested with

the model: (1) All of the NO_3^- in mist chamber samples is from HNO_3 (i.e. $\text{HNO}_{3,\text{initial}}=0.054$ ppb; $\text{NO}_y^*=0.000$). (2) The total decrease in the measured HNO_3^* concentration during the fog is the actual initial HNO_3 atmospheric concentration, and some other NO_y^* species contributes to mist chamber NO_3^- in addition to HNO_3 (i.e. $\text{HNO}_{3,\text{initial}}=0.024$ ppb, $\text{NO}_y^*=0.030$ ppb). Figure 3d shows model results for cases 1 and 2. The modeled HNO_3^* concentrations are determined using equation (8). For case 1 the model predicts that essentially all of the HNO_3^* initially present in the gas phase, in the lowest cell, is transferred to fog droplets within the first several hours of the fog. This is not surprising since HNO_3 is extremely soluble in fog water [Pandis and Seinfeld, 1989a]. However, measurements suggest that only about 40% of the HNO_3^* enters the aqueous phase.

It is possible that the discrepancy between predicted and observed HNO_3^* concentrations may be due to mist chamber sampling artifacts during fog. During sampling, fog droplets collect on the Teflon prefilter of the mist chamber. It is possible that HNO_3 degases from these fog droplets and is collected in the mist chamber (J.E. Dibb, personal communication 1995). This would result in an overestimation

Table 2. Observed and Modeled Fog Fluxes

	Observed Flux, ug/m ²	Modeled Flux, ug/m ²
S(VI)	40	41
N(V)	12	14
H ₂ O ₂	400	310
Fog water, g/m ²	122	80

of the measured gas phase HNO₃* concentration, since some of the HNO₃ sampled is from fog droplets. It is worthwhile to note that the model appears to underpredict the atmospheric concentrations for all of the gas phase species studied, although the discrepancy is most apparent for HNO₃. It is more likely that some other species (NO_y*) contributes to NO₃⁻ in the mist chamber during sampling, or during storage of the samples before analysis. Indeed, NO_y measurements made during the 1994 field season suggest that HNO₃ is only a small fraction of the total NO_y (J.W. Munger, personal communication 1995). If we assume for case 1 that the HNO₃* measurements represent the actual HNO₃ concentrations and that after the first several hours the gas and aqueous phases are in equilibrium, Henry's law estimates that the aqueous phase N(V) concentration should be approximately 500 μM. The measured N(V) concentration in deposited fog droplets is 1.0 μM, which is more than 2 orders of magnitude less than what is expected if HNO₃ is in equilibrium between the gas and the aqueous phase. This is indirect evidence that the mist chamber measures NO₃⁻ from another species, in addition to HNO₃.

The mist chamber measurements show that the HNO₃* concentration decreases by 0.024 ppb during the fog event. Case 2 in Figure 3d assumes that the initial HNO₃ concentration is 0.024 ppb and that the contribution of NO_y* to mist chamber NO₃⁻ has a constant value of 0.03 ppb. In this case, the predicted and observed HNO₃* concentrations are in agreement. Therefore model results suggest that the decrease in the HNO₃* concentration is due to HNO₃ incorporation in fog droplets and that there is likely another chemical species (NO_y*) that contributes to NO₃⁻ in mist chamber samples.

Fluxes of Chemical Species With Fog Droplets

Table 2 shows the predicted and observed fluxes of various chemical species with fog for initial base case concentrations (the base case assumes Table 1 values with an initial HNO₃ concentration of 0.024 ppb). The predicted fluxes of chemical species and fog water generally agree with measurements. The predicted water droplet flux is approximately 30% lower than the measured flux. It is possible that the model underestimates the LWC during fog, which is the critical parameter used to estimate the fog droplet flux. The underprediction of the fog droplet flux may result in lower chemical species fluxes than measured values. This may be the case for H₂O₂, although the chemical species fluxes depend on several factors, the most important being the initial gas and aerosol concentrations. The

Figure 4. Predicted cumulative S(VI) fluxes for SO₂ values of 29 ppt and 0 ppt.

N(V) flux is most likely overestimated by the model due to one or more of the unknown initial concentrations (PAN, NO_x) being higher than the actual concentration. The sensitivity of the fluxes of water and chemical species with fog to the model initial conditions is discussed below.

Sulfate Production in Fog

Figure 4 shows the impact of the initial SO₂ concentration on the predicted deposition of S(VI) due to the aqueous phase oxidation of S(IV) by H₂O₂. The cumulative deposition curves for S(VI) with initial SO₂ concentrations of 29 ppt and 0 ppt are shown in Figure 4. In the absence of SO₂ the deposition of S(VI) is due to the nucleation scavenging of sulfate aerosols by fog droplets. The model predicts that the deposition of S(VI) due to nucleation scavenging of sulfate aerosol is 23 μg/m². This is significantly lower than the measured value of 40 μg/m² given in Table 2. Using the measured initial SO₂ concentration of 29 ppt, the model predicts that the S(VI) flux is 41 μg/m², which agrees with the measured value. This increased depositional flux is due to the conversion of S(IV) to S(VI) by aqueous phase reaction with H₂O₂. The model results suggest that the aqueous phase production of S(VI) accounts for roughly 40% of the total S(VI) deposition, with nucleation scavenging of sulfate aerosols contributing 60%. Unfortunately, uncertainties in the SO₂ measurements make quantitative estimates of the S(VI) deposition due to aqueous phase production uncertain. This model result shows that the deposition of S(VI) with fog at Summit is sensitive to SO₂ concentrations and that accurate measurements of SO₂ are needed to determine the extent to which aqueous phase production of S(VI) may affect deposition.

The initial molar ratio of SO₂ to aerosol SO₄²⁻ for the fog of June 21 is 0.4. The model predicts that both of these species are completely scavenged from the atmosphere by fog, and therefore the SO₂ contributes roughly 40% of the S(VI) fog flux. Aerosol and gas phase measurements made during the 1993 field season at Summit suggest that the atmospheric SO₂/SO₄²⁻ ratio is typically less than 0.30 [Dibb *et al.*, 1994].

Therefore it is possible that a more representative sulfate deposition enhancement due to SO_2 is 30% or less.

N(V) Deposition

There are several nitrogen containing species at Summit that may be responsible directly or indirectly for varying fractions of the deposition of N(V) with fog. These chemical species include NO_x , HNO_3 , and PAN. Figure 5 shows the predicted effect of the assumed initial atmospheric concentrations of NO_x , HNO_3 , and PAN on the deposition of N(V) with fog. For case 1 in Figure 5 the base case initial atmospheric concentrations are assumed with HNO_3 and PAN equal to zero. In this case, the N(V) fog flux is due primarily to the gas phase conversion of NO_2 to HNO_3 [Carter and Atkinson, 1988]:

During the fog event, fog droplets absorb UV solar radiation (we assume a photolytic reduction of 50% within the fog layer) and reduce the photolytic production of OH. A second path of HNO_3 production exists as follows [Russell et al., 1986]: NO_2 reacts with O_3 to create the nitrate radical

During the day, NO_3 is photochemically destroyed, but inside the fog layer the destruction is slowed due to the decrease in UV radiation. The following reaction then occurs:

N_2O_5 will then react with water vapor as follows [Carter and Atkinson, 1988]:

This equation neglects the possible heterogeneous reaction of N_2O_5 with water droplets. For the atmospheric conditions at Summit the rate of production of N_2O_5 during fog from (R3) is typically 1/3 the rate of destruction from (R4). Therefore increasing the rate constant of (R4) to consider heterogeneous chemistry on the surface of fog droplets in this case does not influence the production of N(V), since (R3) is the rate limiting step. For case 1 the total N(V) deposition with fog droplets is $4.6 \mu\text{g}/\text{m}^2$. The $\text{NO}_2 + \text{OH}$ reaction accounts for 65% of the HNO_3 formation, with the $\text{N}_2\text{O}_5 + \text{H}_2\text{O}$ accounting for the other 35%. (R1) is sensitive to the OH concentration and the model predicts that the OH concentrations range from 0.3×10^5 molecules/ cm^3 in the middle of the fog event to 0.6×10^6 molecules/ cm^3 at 0600 on June 22 immediately after the fog event. These values generally agree with the values expected for the Arctic free troposphere during the middle of the summer [Jacob et al., 1992].

For case 2 in Figure 5, base case atmospheric

Figure 5. Predicted cumulative N(V) fluxes for case 1 (base case with HNO_3 and PAN equal to zero), case 2 (base case with HNO_3 and PAN equal to 0.024 and 0.000 ppb, respectively), case 3 (base case with HNO_3 and PAN equal to 0.024 and 0.540 ppb, respectively), and case 4 (base case with HNO_3 and PAN equal to 0.024 and 5.000 ppb, respectively).

concentrations are assumed with initial HNO_3 and PAN concentrations of 0.024 ppb and 0 ppb, respectively. In this case the aqueous phase N(V) originates from the initial HNO_3 concentration as well as from (R1) and (R4). The total N(V) flux is $12.9 \mu\text{g}/\text{m}^2$, which suggests that approximately 65% of the N(V) flux is due to the incorporation of the initial HNO_3 in fog droplets.

Case 3 assumes base case atmospheric concentrations with HNO_3 and PAN concentrations of 0.024 ppb and 0.54 ppb, respectively. In this case additional N(V) is deposited to surface snow due to the decomposition of PAN in both the gas and the aqueous phases. The gas phase decomposition of PAN is as follows [Atkinson and Lloyd, 1984]:

NO_2 then forms HNO_3 through (R1) and (R4). N(V) may also be produced due to the partitioning of PAN between the gas and the aqueous phase and the following reaction [Lee, 1984]:

Figure 5 shows that for case 3, PAN decomposition contributes about 10% to the flux of N(V) with fog. The gas and aqueous phase production of N(V) in the lower 200 m of the atmosphere for case 3 atmospheric concentrations is shown in Figure 6. (R1) accounts for 65% of the N(V) formation, with 30% being contributed from (R4), and 5% from (R5). It is worthwhile to note that (R6) accounts for about 20% of the N(V) production from PAN, with (R5) accounting for the majority of the production through the formation of NO_2 and subsequent reactions to make HNO_3 .

Figure 6. Contributions of reactions (1), (4), and (6) to the cumulative N(V) flux.

As mentioned earlier, NO_y values measured during the 1994 summer field season ranged from 0.3 ppb to 5.0 ppb. Case 4 assumes base case concentrations, with an initial PAN concentration equal to the upper limit NO_y value of 5.0 ppb. For this case the results show that PAN can have a significant effect on the deposition of N(V) and accounts for about 40% of the total N(V) deposition with fog.

Unfortunately, there are neither direct PAN nor NO_y measurements available for the 1993 field season. Indeed, PAN concentration measurements have not been made at Summit and the range of PAN values is based on NO_y measurements made during the 1994 field season. Values of PAN reported during summer in the Arctic free troposphere from ABL 3A [Singh *et al.*, 1992] and ABL 3B [Fan *et al.*, 1994] are typically from 0.1 ppb to 0.5 ppb. Therefore it is likely that the actual PAN concentration at Summit is closer to 0.54 ppb than to 5.0 ppb. Figure 5 is merely meant to show the importance of the relative contributions of nitrogen-containing species HNO_3 , NO_2 , and PAN to the deposition of N(V).

Sensitivity of Estimated Fog Fluxes to Model Parameters

Several model parameters are relatively uncertain and the sensitivity of our conclusions to their selected base case values is investigated in this section. In particular, the sensitivity of the modeled fog water and chemical species fluxes to the fog droplet settling velocity parameterization as well as the initial relative humidity profile and accommodation coefficient will be explored.

Settling Velocity Parameterization

In the base case simulations we assume that the fog droplet settling velocity parameter, a_g , is $0.20 \text{ m}^4/\text{g s}$. This is based on FSSP measurements made by Borys *et al.* [1992]. The a_g values estimated from the measurements range from about $0.1 \text{ m}^4/\text{g s}$ to $0.4 \text{ m}^4/\text{g s}$. Table 3 shows the percentage fog flux difference from the base case for a_g values of $0.1 \text{ m}^4/\text{g s}$ and $0.4 \text{ m}^4/\text{g s}$. For $0.1 \text{ m}^4/\text{g s}$ the fog lasts for 20 min less than the base case, grows to approximately the same height, and has a mean liquid water content about 25% greater than the base case. The total fluxes of S(VI), H_2O_2 , and N(V) are approximately 20% less than the base case since both the fog duration and the liquid water flux are less.

Table 3 shows that for an a_g value of $0.4 \text{ m}^4/\text{g s}$ the water droplet flux increases by 6% of the base case. For $0.4 \text{ m}^4/\text{g s}$ the fog lasts about 30 min longer than the base case and has a mean liquid water content that is 15% less than the base case value. The chemical species fog fluxes increase by approximately 20% due to greater fog droplet settling velocities. Although the greater a_g value generally results in a lower liquid water content, the droplets are more concentrated and the result is an increase in chemical species fluxes. Model results suggest that the settling velocity parameterization introduces uncertainties of roughly 20% in the estimated fog fluxes.

Relative Humidity Profile

We assumed for our base case simulations that the initial RH profile (RH_i) is constant at 0.88 for the 400-m fog model domain. The assumption was necessary since RH profile

Table 3. Modeled Fog Flux Sensitivities to a_g , RH_i , and a_w

	Modeled Fog Flux Sensitivities to a_g , RH_i , and a_w					
	Percentage Fog Flux Difference From Base Case ($a_g=0.2$)		Percentage Fog Flux Difference From Base Case ($\text{RH}_i=0.88$)		Percentage Fog Flux Difference From Base Case ($a_w=0.01$)	
	$a_g=0.1$	$a_g=0.4$	$\text{RH}_i=0.80$	$\text{RH}_i=0.95$	$a_w=0.0001$	$a_w=0.1$
S(VI)	-24	21	-40	17	0.5	-0.4
N(V)	-24	16	-39	35	31	-3
H_2O_2	-20	23	-34	17	26	-1
Fog water, g/m^2	-6	6	-44	34		

Figure 7. Predicted cumulative N(V) fluxes for a_w values of 0.0001, 0.01, and 0.1.

measurements are not available for Summit. Table 3 shows the sensitivity of the fog model to RH_i values. When RH_i is 0.95 the fog grows to approximately the same height as the base case, with the same duration and a mean LWC about 30% greater. The liquid water flux is 34% greater than the base case, and the fluxes of S(VI) and H_2O_2 are 17 % greater, with the N(V) flux being 35% greater. The results in Table 3 generally show that the chemical and fog water fluxes are sensitive to the initial relative humidity profile and that for a wide range of initial relative humidities the chemical species fluxes are generally within 40% of the base case. The sensitivity of the model to the RH profile points out the importance of measuring this parameter at Summit.

Accommodation Coefficient

We have assumed so far that the accommodation coefficient, a_w , for all gas phase chemical species is 0.01 [Pandis and Seinfeld, 1989b]. This is due to the lack of experimental data available on the accommodation coefficients of chemical species for the low temperatures observed in Greenland. Worsnop *et al.* [1989] report a_w values for SO_2 and H_2O_2 at 273 K of roughly 0.20. Van Doren *et al.* [1990] report that a_w for HNO_3 decreases from about 0.2 at 293 K to 0.07 at 268 K. Table 3 shows the sensitivity of the fog fluxes to the accommodation coefficient. We have chosen a lower limit accommodation coefficient value of 0.0001, and an upper limit value of 0.1. Table 3 shows that decreasing a_w increases the fluxes of N(V) and H_2O_2 . This is apparently counterintuitive, since one expects that decreasing the frequency at which molecules of HNO_3 and H_2O_2 stick to the surface of droplets decreases the aqueous phase concentrations. The flux increases occur since the decrease in a_w also results in slower aqueous phase uptake of HO_2 and therefore relatively greater gas phase concentrations of both HO_2 and OH. This results in an increase in gas phase HNO_3 production due to (R1). This agrees with model results presented by Schwartz [1984]. The H_2O_2 gas phase

concentrations increase due to the reaction of 2 HO_2 molecules to form H_2O_2 . The gas phase chemical species are eventually transferred to the aqueous phase, despite the much greater base case a_w value. The result is that the droplets are initially less concentrated with respect to HNO_3 and H_2O_2 and eventually become more concentrated towards the middle of the fog event. Figure 7 illustrates this point, by presenting the N(V) flux for values of a_w ranging from 0.0001 to 0.1. Figure 7 shows that for an a_w of 0.0001 the cumulative flux for the first several hours of the fog is less than for the base case and eventually surpasses the base case flux as the droplets become more concentrated. Figure 7 shows that for a_w values greater than 0.01 the N(V) flux is relatively unchanged since the mass transport rate is unaffected by increases in a_w after this point [Schwartz, 1984]. The flux of SO_2 is relatively unaffected by changes in a_w since the concentration of S(VI) in the aqueous phase is independent of changes in atmospheric OH and HO_2 .

As a_w decreases below 0.0001, the fog fluxes of S(VI) and N(V) begin to decrease since the mass transport of gases to the droplet surfaces becomes increasingly small. As a_w approaches zero the flux of gases also goes to zero [Pandis and Seinfeld, 1989b]. It is difficult to assess the validity of the lower limit a_w value of 0.0001, since measurements of organic species in fogs have not been made at Summit.

Impact of Fog Model Results on Ice Core Interpretation

The deposition of aerosols and gases with fog can significantly influence the summer surface snow chemical composition at Summit [Bergin *et al.*, 1994; Dibb *et al.*, 1994]. The relative contributions of fog to the 1993 summer inventories of S(VI) and N(V) are approximately 30% and 10%, respectively [Bergin *et al.*, 1995b]. Unfortunately, the contribution of fogs to the annual chemical species fluxes has not yet been estimated, since field campaigns have not taken place during the winter. Observations reported from Dye 3 central Greenland show that the frequency of fogs generally increases during the winter months [Bergin *et al.*, 1994], although this lower latitude sight is closer to the coast and may be more influenced by advective fogs than Summit.

To estimate the contributions of fog deposition to annual chemical signals it is necessary to know not only the frequency of fog events throughout the year but also the atmospheric concentrations of the gases and aerosols present during the fogs. If we assume that fog significantly influences the annual fluxes of various chemical species at Summit, the model results suggest that the relationship between the atmospheric gas phase concentrations and the deposition of chemical species with fog is complicated by the fact that several gas phase species can contribute to a single surface snow chemical signal. Model results show that the N(V) fog flux is sensitive to the initial concentrations of NO_2 , PAN, and HNO_3 . Results also suggest that both aerosol sulfate and gas phase SO_2 contribute to the deposition of S(VI) with fog, although it is likely that SO_2 typically contributes to roughly 30% or less of the S(VI) fog flux. Current measurements of

SO₂ have a great deal of uncertainty making it difficult to accurately assess the role of SO₂ on S(VI) fog flux. Similarly, measurements of PAN, NO₂, and other organic nitrates that may contribute to the fog N(V) flux have not been directly measured at Summit. It is possible that the relative concentrations of the gas phase species changes throughout the year. For instance, *Bottenheim et al.* [1994] show that PAN concentrations in eastern Canada are significantly higher in the winter than in the summer. This suggests that the aqueous phase formation of N(V) by PAN may be important during winter months. It is also possible that nighttime chemistry plays a role in creating N(V) from NO₂ during the winter. Since dry deposition is negligible compared to the fog fluxes of chemical species during a fog event [*Bergin et al.*, 1994], we have ignored the impact of dry deposition on snow chemistry. It is possible that dry deposition of gas phase chemical species affects the annual chemical signals, although the lack of atmospheric concentration measurements makes it extremely difficult to estimate the annual contribution of dry deposition to surface snow chemical signals. It is important to note that snow crystals may contain a quasi-liquid layer [*Conklin and Bales*, 1993] and it is therefore possible that similar chemistry observed during fogs occurs in clouds and in deposited surface snow. Overall, the model results suggest that estimates of past atmospheric chemistry of N(V) and S(VI) based on ice core chemistry should consider the direct and indirect contributions of various gas phase chemical species. This is particularly clear for N(V) fog deposition, which depends on the relative atmospheric concentrations of NO₂, HNO₃, and PAN.

Conclusions

A Lagrangian model originally developed by *Pandis and Seinfeld* [1989a] to predict the fluxes of acidic species during fog events in Southern California has been modified and applied to a fog event at Summit, Greenland. The model is used to predict the evolution of the atmospheric LWC profile during a radiation fog, as well as detailed gas and aqueous phase chemistry, and the deposition of chemical species that include S(VI), N(V), and H₂O₂. The model is also used to assess the contribution of various gas phase species to the deposition of S(VI) and N(V).

The observed and predicted temperature profiles during the fog event are in close agreement. This indicates that the model adequately accounts for the transport of heat in the atmosphere, and at the air/snow interface. The ability of the model to follow dynamic changes in atmospheric temperature suggests that the transport of water vapor, and fog formation, is correctly modeled.

The atmospheric concentrations of HCOOH and H₂O₂ during the fog event generally agree with measurements. Comparison between the modeled and the measured HNO₃ concentrations suggests that the mist chamber probably measures additional NO_y species. The model underestimates the SO₂ concentrations during fog. This may be due to uncertainties in the measured values.

The fluxes of liquid water, S(VI), N(V), and H₂O₂ with fog generally agree with measured values. Model results estimate that heterogeneous SO₂ oxidation by H₂O₂ contributes to approximately 40% of the S(VI) flux during the fog event, with the remaining 60% coming from the preexisting sulfate aerosol. Although direct measurements of PAN and NO₂ are not available for the fog event, model results based on likely atmospheric concentrations of these species indicate that they may significantly contribute to the deposition of N(V) with fog. Furthermore, if a quasi-liquid layer indeed exists on the surface snow at Summit, similar reactions occurring in fog droplets may also influence snow chemistry.

The fog droplet settling velocity parameter, a_g , as well as the initial relative humidity profile, RH_i, significantly influence the fluxes of chemical species with fog. For the likely range of values for a_g and RH_i the fog fluxes vary by 20% and 30%, respectively. Also, the fog fluxes of N(V) and H₂O₂ increase by roughly 30% as the accommodation coefficient is decreased from 0.01 to 0.0001. This is due to increased gas phase HNO₃ production at lower a_w values due to a decrease in the partitioning of HO₂ in the aqueous phase.

Model results suggest that accurate measurements of SO₂, NO₂, HNO₃, and PAN are needed to accurately estimate the flux of S(VI) and N(V) during fogs at Summit. Also, measurements of the initial prefog relative humidity profiles are needed, since the chemical species fluxes with fog are relatively sensitive to this parameter.

Model results suggest that it is important to quantify the frequency and chemical composition of fog events throughout the year at Summit so that the direct contribution of fogs to annual chemical signals can be determined. It is also necessary to measure the atmospheric concentrations of the gas phase chemical species contributing to S(VI) and N(V) fog deposition so that the chemistry associated with fog deposition can be better understood. It is important to point out that similar chemistry observed during fogs may occur in ice crystals in clouds as well as in deposited surface snow. Model results generally suggest that estimates of past atmospheric chemistry of N(V) and S(VI) based on ice core chemistry may need to consider the direct and indirect contributions of various gas phase chemical species.

Acknowledgments. We would like to thank Sally Whitlow for advice concerning the IC analyses. We also thank Mark Losleben and Roger Bales for measuring H₂O₂ in the air and in fog samples.
