ABSTRACT: Selective logging is an extensive land use in the Brazilian Amazon region. The soil–atmosphere fluxes of nitrous oxide (N_2O), nitric oxide (NO), methane (CH_4), and carbon dioxide (CO_2) are studied on two soil types (clay Oxisol and sandy loam Ultisol) over two years (2000–01) in both undisturbed forest and forest recently logged using reduced impact forest management in the Tapajos National Forest, near Santarem, Para, Brazil. In undisturbed forest, annual soil–atmosphere fluxes of N_2O (mean $\pm$ standard error) were 7.9 ± 0.7 and 7.0 ± 0.6 $\text{ng N cm}^{-2} \text{ h}^{-1}$ for the Oxisol and 1.7 ± 0.1 and 1.6 ± 0.3 $\text{ng N cm}^{-2} \text{ h}^{-1}$ for the Ultisol for 2000 and 2001, respectively. The annual fluxes of NO from undisturbed forest soil in 2001 were 9.0 ± 2.8 $\text{ng N cm}^{-2} \text{ h}^{-1}$ for the Oxisol and 8.8 ± 5.0 $\text{ng N cm}^{-2} \text{ h}^{-1}$ for the Ultisol. Consumption of CH_4 from the atmosphere dominated over production on undisturbed forest soils. Fluxes averaged -0.3 ± 0.2 and -0.1 ± 0.9 $\text{mg CH}_4 \text{ m}^{-2} \text{ day}^{-1}$ on the Oxisol and -1.0 ± 0.2 and -0.9 ± 0.3 $\text{mg CH}_4 \text{ m}^{-2} \text{ day}^{-1}$ on the Ultisol for years 2000 and 2001. For CO_2 in 2001, the annual fluxes averaged 3.6 ± 0.4 $\mu\text{mol m}^{-2} \text{ s}^{-1}$ on the Oxisol and 4.9 ± 1.1 $\mu\text{mol m}^{-2} \text{ s}^{-1}$ on the Ultisol. We measured fluxes over one year each from two recently logged forests on the Oxisol in 2000 and on the Ultisol in 2001. Sampling in logged areas was stratified from greatest to least ground disturbance covering log decks, skid trails, tree-fall gaps, and forest matrix. Areas of strong soil compaction, especially the skid trails and logging decks, were prone to significantly greater emissions of N_2O , NO , and especially CH_4 . In the case of CH_4 , estimated annual emissions from decks reached extremely high rates of 531 ± 419 and 98 ± 41 $\text{mg CH}_4 \text{ m}^{-2} \text{ day}^{-1}$, for Oxisol and Ultisol sites, respectively, comparable to wetland emissions in the region. We calculated excess fluxes from logged areas by subtraction of a background forest matrix or undisturbed forest flux and adjusted these fluxes for the proportional area of ground disturbance. Our calculations suggest that selective logging increases emissions of N_2O and NO from 30% to 350% depending upon conditions. While undisturbed forest was a CH_4 sink, logged forest tended to emit methane at moderate rates. Soil–atmosphere CO_2 fluxes were only slightly affected by logging. The regional effects of logging cannot be simply extrapolated based upon one site. We studied sites where reduced impact harvest management was used while in

typical conventional logging ground damage is twice as great. Even so, our results indicate that for N_2O , NO , and CH_4 , logging disturbance may be as important for regional budgets of these gases as other extensive land-use changes in the Amazon such as the conversion of forest to cattle pasture.

KEYWORDS: Selective logging; Trace gas; Tropical forest

1. Introduction

Selective logging is an extensive land use in the Amazon region of Brazil and in other tropical forest areas. According the Brazilian Institute for Geography and Statistics (IBGE), the volume of round-wood production in the Brazilian Amazon between 1991 and 2000 was $3.5 \times 10^7 \text{ m}^3 \text{ yr}^{-1}$ (<http://www.igbe.br/>). Assuming a nominal harvest volume between 20 and $30 \text{ m}^3 \text{ ha}^{-1}$ this implies that in an average year approximately 1.8×10^6 to $1.2 \times 10^6 \text{ ha}$ were affected by logging during the 1990s. Based on a survey of sawmills conducted in 1996–97, Nepstad et al. (Nepstad et al. 1999) estimated that approximately 1.0 to $1.5 \times 10^6 \text{ ha yr}^{-1}$ were logged. The area of forest selectively logged each year in the Brazilian Amazon is similar to the area of forest cleared for pastoral and agricultural uses (Houghton et al. 2000).

Selective logging in the Brazilian Amazon generally involves felling and yarding (transport of timber from the cut site to the roadside) of 1–9 trees ha^{-1} . Although relatively few trees are intentionally felled, selective logging causes substantial damage to the remaining forest stand (Ewel and Conde 1980). In the Brazilian Amazon in the municipality of Paragominas, Para, Verissimo et al. (Verissimo et al. 1992) found that on average 27 trees were damaged for each tree harvested and 38% of the canopy was destroyed at a harvest intensity of 6.4 trees ha^{-1} ($38 \text{ m}^3 \text{ ha}^{-1}$). Ground damage can also be severe. Johns et al. (Johns et al. 1996) found that in unplanned operations in Paragominas, approximately 15% of the ground area was affected by heavy machinery when 5.6 trees ha^{-1} were harvested ($30 \text{ m}^3 \text{ ha}^{-1}$). Logging damage depends upon the logging practices employed. Also, working in the Paragominas municipality, Pereira et al. (Pereira et al. 2002) found that both ground damage and canopy damage could be reduced by about 50% under reduced impact logging (RIL) harvest management compared to conventional logging (CL) practice.

Soil–atmosphere exchange of carbon dioxide (CO_2), nitric oxide (NO), nitrous oxide (N_2O), and methane (CH_4) is controlled by complex biogeochemical processes (Conrad 1996). Tropical forests have high rates of biological productivity and rapid decomposition rates of organic matter because of abundant solar radiation, high temperature, and heavy precipitation. High nitrogen availability coupled with high moisture content makes tropical forest soils especially likely to emit N_2O and NO (Davidson et al. 2000). The soils of tropical forests are globally important sources of both N_2O and NO (Matson and Vitousek 1990; Davidson and Kinglerlee 1997). Well-drained upland soils generally consume CH_4 from the atmosphere and soil moisture content regulates the flux through its control on the diffusion of CH_4 into the soil (Crill 1991; Born et al. 1990). Tropical forest soils can change from a sink to a source of CH_4 depending upon soil moisture conditions and land use (Keller et al. 1990; Keller and Reiners 1994; Steudler et al. 1996).

Selective logging affects the forest canopy, microclimate, soil physical conditions, and biogeochemical cycling (Pereira et al. 2002; McNabb et al. 1997; Brouwer 1996). We asked whether these changes would affect carbon dioxide (CO₂), nitric oxide (NO), nitrous oxide (N₂O), and methane (CH₄) exchange between forest soils and the atmosphere. We measured soil–atmosphere flux of these four trace gases on both Ultisol and Oxisol soils in both undisturbed and logged forests over two full years.

2. Methods

2.1. Site description

We conducted our study in the Tapajos National Forest (TNF) near km 83 on the Santarem–Cuiaba Highway (3.04°S, 54.95°W) south of Santarem, Para, Brazil. The Brazilian Institute for the Environment and Renewable Resources (IBAMA) administered a demonstration logging project at this site. Logging by a commercial enterprise began in December 1999. Only one 100-ha survey and management block (quad 2, block 3) was harvested in the TNF during 1999 because of a delayed start in operations. In 2000, nearly 1000 ha were logged by the commercial operator. In 2000 we measured trace gas fluxes in the 100-ha block that was harvested in December 1999. In 2001, we made measurements on a second 100-ha block (quad 2, block 9) that had been logged in September 2000.

The TNF receives approximately 2000 mm of precipitation per year and has an annual mean temperature of 25°C (Silver et al. 2000). The rainy season extends from late December or early January through June. The duration of the rainy period varies from year to year. For purposes of comparison, we consider January through June the rainy period. Most logging operations are conducted in the dry season from July through December. Vegetation at the site is evergreen, mature tropical forest with a total biomass of about 372 Mg ha⁻¹ (Keller et al. 2001). The most common timber species harvested during 2000 were *Manilkara huberi*, *Carapa guianensis*, *Couratari guianensis*, *Licaria brasiliensis*, and *Nectandra rubra*. The most common tree species [>35 cm diameter at breast height (DBH)] found are *Pouteria* sp., *Manilkara huberi*, *Carapa guianensis*, *Eschweilera* sp., and *Sclerolobium melanocarpum*. The study site is located on an old, nearly flat, erosional remnant plateau with well-drained soils. We located our undisturbed forest measurements on contrasting soils, a clay-textured Oxisol (80% clay, 18% sand, 2% silt in 0–10 cm) and a sandy-loam-textured Ultisol (60% sand, 38% clay, 2% silt in 0–10 cm) (Silver et al. 2000). Both soils (0–10 cm) were acid with a pH of about 3.9 and 4.2 in the Ultisol and Oxisol, respectively. The soils had similar total C of about 2.5% in the top 10 cm. The Ultisol had slightly less total N in the top 10 cm (0.14%) as compared to the Oxisol (0.18%) (Silver et al. 2000). The logging operation studied in 1999 was located on the clay-textured Oxisol. In 2000, we studied logging on an Ultisol similar to the undisturbed forest site.

Within a selectively logged area, the degree of soil compaction and modification of microclimate and biogeochemical processes varies greatly according to harvest practice. Within the studied logging sites at TNF, we stratified sampling according to decreasing damage intensity from logging decks, skid trails, felling gaps to relatively undisturbed forest (Figure 1). Excluding roads where we did not sample

Figure 1. Map of mechanical soil disturbance (roads, decks, and skid trails) in a 100-ha forest area at the Tapajos National Forest logged in Dec 1999.

gas fluxes, the greatest damage was found on the log storage decks (or landings). Logs were skidded to these locations and stored prior to loading on trucks for transport to the mill. On decks, all vegetation was removed and the soil was compacted as a result of frequent passes of skidding and loading machinery. Decks were cleared by a tracked bulldozer so topsoil and organic matter were scraped off.

In the logging operations at TNF, articulated wheeled skidders were used to skid logs to the decks. Because logging at this site was planned, skid trails covered the logging blocks in a dendritic pattern (Figure 1). The primary skids were the central stems of the trail system. Secondary skids were the branches. In this planned system, many more trips were made along primary skid trails than along secondary trails. The tree-fall gap (hereafter gap) was the ground area where the harvest tree and collaterally damaged trees fell. This zone was extremely heterogeneous. In places it was characterized by bare soil while in other places it was covered by tangles 2 m or more high of fine and coarse debris. Areas within the logging block that were not decks, skid trails, or gaps were considered forest matrix. Holmes et al. (Holmes et al. 2002) and Pereira et al. (Pereira et al. 2002) provide more details on forest harvest practices and logging damage for a similar site in eastern Para.

2.2. Field sampling of soil gas flux

Undisturbed forest sites were sampled on 31 dates from 4 February 2000 through 26 February 2002. Measurements of soil–atmosphere flux for N_2O and CH_4 as well as soil water-filled pore space (WFPS) covered this full period, while measurements of fluxes of NO and CO_2 commenced on 10 October 2000 and continued through the end of the study period. The Oxisol and Ultisol sites were sampled on the same day, generally between 0800 and 1800 local time. When all systems were operational, fluxes for all four gases were measured from eight chambers at randomly selected points along 30-m transects. After gas flux sampling was completed, soil samples were removed from each gas sampling location for determination of soil moisture content.

For the logging sites, in 2000, we randomly selected a focal site that we sampled approximately monthly. At that site, we measured fluxes in four sampling strata: the focal deck, adjacent skid trails, gaps, and background forest matrix areas. We defined the forest matrix as those areas more than 10 m distant from decks, skid trails, and gaps. Skid trail measurements were alternated between primary and secondary skid trails. On other dates, we made measurements at other randomly selected sites. In the first half (wet season) of 2000, these additional measurements were purposely biased toward decks and skid trails. On each sampling date, flux chamber locations within each stratum were randomly selected along 30-m transects in a manner similar to their selection within the undisturbed forest. For skid trails, transects were aligned diagonally across the trails in order to cross the tire ruts and the raised area between the ruts.

We sampled gas fluxes using enclosures consisting of a section of polyvinylchloride pipe (0.25-m diameter) that served as a base and an acrylonitrile–butadiene–styrene cap that fit snugly on the base. The combination of base plus cap was nearly cylindrical with a height of about 20 cm when inserted into the soil. Bases were inserted at most 30 min prior to flux measurements and they were removed immediately after completion of flux measurements in order to avoid artifacts related to root mortality from chamber insertion (Keller et al. 2000; Varner et al. 2003). Dynamic open chambers were used for measurement of NO and CO_2 (Varner et al. 2003), and static vented chambers were used for measurements of N_2O and CH_4 (Keller and Reiners 1994). The measurement of these two pairs of gases was sequential, in a haphazard order, after lifting the chamber top to equilibrate the head space with ambient air.

2.3. Field analytical system for NO and CO₂

We used an integrated flow system to measure NO and CO₂. The chamber flow rate was regulated to about 300 cm³ min⁻¹. Air entered the chamber through a chimney-like air gap that was specifically designed to minimize exchange with the outside air and to avoid pressure fluctuations within the chamber (Rayment and Jarvis 1997). Using this design, the pressure differential between the chamber and the outside air was less than 0.004 Pa in laboratory tests. The chamber base was capped for 3 to 10 min.

Air flowed from the soil enclosure through a Teflon-lined polyethylene sample line 30 m in length and then it entered an infrared gas analyzer (Li-Cor 6262) for CO₂ measurement. From the Li-6262, the sampled air then passed through a flow control manifold where it was mixed with a makeup airflow of about 1200 cm³ min⁻¹ and a flow of NO (1 ppm) in oxygen-free nitrogen standard gas that varied from 3 to 10 cm³ min⁻¹ as measured on an electronic mass flowmeter (Sierra Top-Trak). The flowmeter was checked occasionally against a NIST-traceable electronic bubble flowmeter (Giliblator). The makeup air and standard additions maintained optimum and linear performance of the NO₂ chemiluminescent analyzer (Scintrex LMA-3) according to the manufacturer's recommendations. The mixed sample stream passed through a Cr₂O₃ catalyst for conversion of NO to NO₂ (Levaggi et al. 1974). The NO₂ chemiluminescent analyzer was standardized by a two-point calibration approximately hourly.

Frequent standardization in the field was necessary because the LMA-3 was relatively unstable under the changing temperature, humidity, and background contaminant levels found in the field. Varner et al. (Varner et al. 2003) found that intraday variation in standards could be as great as 60% even after accounting for linear drift between the beginning and the end of a measurement day. We also compared the concentration of the field NO standard periodically with laboratory standards to assure that they did not drift (Veldkamp and Keller 1997).

Signals from the CO₂ and NO₂ analyzers and the mass flowmeter for the NO standard gas were recorded on a datalogger (Campbell CR10). Fluxes were calculated from the linear increase of concentration versus time adjusted for the ratio of chamber volume to area and the air density within the chamber.

2.4. Analysis of CH₄ and N₂O

We made static enclosure measurements for CH₄ and N₂O fluxes using the same bases and vented caps (Keller and Reiners 1994). Four enclosure headspace samples were taken over a 30-min sampling period with 20-mL nylon syringes. Analysis of grab samples for CH₄ and N₂O were completed within 36 h by FID and ECD gas chromatography. Gas concentrations were calculated by comparing peak areas for samples to those for commercially prepared standards (Scott-Marin) that had been calibrated against the LBA-ECO (a component of the Large-Scale Biosphere–Atmosphere Experiment in Amazonia) standards prepared by the National Oceanic and Atmospheric Administration/Climate Monitoring and Diagnostic Laboratory (NOAA/CMDL). Fluxes were calculated similarly to those for CO₂ and NO.

2.5. Determination of soil WFPS

Soil samples were taken to 10-cm depth in each chamber location on each date for determination of soil moisture (oven dried at 105°C). Soil moisture was expressed as WFPS using soil bulk densities of 1.25 and 1.02 for Ultisol and Oxisol soils, respectively, at the undisturbed forest sites (Silver et al. 2000). Bulk densities for the logged sites were measured as described below. We recorded air and soil (2-cm depth) temperature using thermistor probes to accompany each soil enclosure measurement. Precipitation was measured daily using a manual rain gauge in an open field approximately 3–7 km from the various study areas.

2.6. Ground damage and calculation of excess trace gas fluxes

The full 100-ha management block logged in 1999 was mapped on the ground using methods described by Pereira et al. (Pereira et al. 2002). Location and dimensions were measured for all roads, decks, and skid trails. We calculated the proportion of the soil area affected by mechanical disturbance using a geographic information system. We only measured logging damage for the Oxisol site logged in 1999. We applied these damage estimates for the Ultisol site in order to estimate excess flux. The approximate area covered by gaps was estimated by comparison to similarly logged sites in eastern Para assuming a gap radius of 20 m per harvested tree characteristic of RIL and a harvest density of 3.5 trees ha⁻¹ (Asner et al. 2004).

To quantify the effect of logging on trace gas fluxes, we calculated an excess flux ($\Delta f_i = f_i - f_{\text{background}}$) that could be attributed to logging for a specific sampling stratum by subtracting the forest background ($f_{\text{background}}$) values from the flux for that stratum (f_i). We used data from the forest matrix within the logging sites or the undisturbed forest for background fluxes. As noted below, the forest matrix values generally were statistically indistinguishable from the nearby undisturbed forest sites. The integrated change (ΔF) in flux that can be attributed to logging was calculated as

$$\Delta F = \sum (A_i/A_T) \Delta f_i, \quad (1)$$

where A_i is the area for a given sampling stratum and A_T is the total area subject to the constraint that $\sum A_i = A_T$.

Errors in the calculation ΔF depend upon both errors in the area determinations and in the errors in flux measurement. We have no estimate of error for the area measurements so we have made an error estimate for ΔF based only on the error in excess flux ($E_{\Delta f_i}$). This error depends on the sampling error of the independent components of Δf_i :

$$E_{\Delta f_i} = (E_{f_i}^2 + E_{f_{\text{background}}}^2)^{0.5}. \quad (2)$$

Because of the large dispersion in flux measurements, we expect this error to dominate over any error in area estimation. We estimate the error on the excess flux as

$$E_{\Delta F} = \{\sum [(A_i/A_T) E_{\Delta f_i}]^2\}^{0.5}. \quad (3)$$

A notable feature of ground damage is soil compaction caused by heavy machinery. We quantified soil compaction by measurement of bulk density for the 0–10-

cm layer in all four logging strata in blocks logged in 1999 and 2000 using 300-cm³ stainless steel rings to remove intact cores (Blake and Hartge 1986). Eight undisturbed cores were removed from random locations for each sampling stratum in each logging block.

2.7. Statistical analysis

Annual average fluxes were computed as the averages of wet- (January to June) and dry-season (July to December) fluxes in order to avoid bias resulting from unequal numbers of samples in each season. The error for the annual flux was propagated from the standard error of the seasonal fluxes (SE_{wet} and SE_{dry}) by addition in quadrature with adjustment for $n = 2$ in the average (Bevington 1969, p. 60):

$$\text{Annual error} = 0.5 * (SE_{\text{wet}}^2 + SE_{\text{dry}}^2)^{0.5}. \quad (4)$$

We compared daily mean fluxes of trace gases, soil moisture, soil temperature, and air temperature for both undisturbed forest using a two-way analysis of variance (ANOVA) with factors for soil type and season as well as a soil by season interaction term. For logged sites, we employed a two-way ANOVA to test for effects of season and damage stratum. In both cases, the replicates are individual sampling dates; chambers' locations were chosen randomly for each date. We applied a log-transformation to CH₄ and N₂O flux data at logged sites in order to homogenize variances for the ANOVA model. It was necessary to add a small positive value to CH₄ fluxes prior to log-transformation for ANOVA to avoid transformation of negative values (soil consumption of CH₄). For soil effects or logging stratum effects within a focal site, the samples may be considered pseudoreplicates (Hurlbert 1984) and we caution that conclusions based upon the statistical tests should not be extended beyond the narrow range of the study sites. We also used ANOVA to test for differences in bulk density for the various damage strata in logged blocks.

3. Results

3.1. Soil moisture and trace gas fluxes in undisturbed forest

Although our definition of rainy and dry seasons was somewhat arbitrary, the wet periods of January through June received 1783 and 1738 mm of rain for 2000 and 2001, respectively, compared to the dry periods that received only 576 and 188 mm. On undisturbed forest sites, soil moisture content varied significantly (ANOVA, $p < 0.0001$) by season and by soil type (Figure 2e). Soil moisture was substantially greater when measured during the wet season (January–June) than during the dry season (July–December). Over 2 yr of sampling, wet-season WFPS averaged ($\pm$ standard error) 48.3% (± 2.0) and 37.8% (± 3.0) for the clay Oxisol and sandy loam Ultisol, respectively, in the top 10 cm. In the dry season the Oxisol and Ultisol soil WFPS fell to an average ($\pm$ standard error) of 33.1% (± 3.0) and 23.0% (± 2.6) (Figure 2e). Soil temperature at 2-cm depth (not shown) was significantly different by season (ANOVA, $p < 0.001$), with average temperatures of 24.7° and 25.4°C in the wet and dry seasons, respectively. There was no significant difference in temperature across soil type.

Figure 2. Seasonal patterns of soil-atmosphere trace gas fluxes, soil WFPS, and daily precipitation (gray bars) from undisturbed forest sites on a clay Oxisol and a sandy loam Ultisol in the Tapajos National Forest from 4 Feb 2000 through 26 Feb 2002. Error bars represent standard errors of the mean for individual sampling dates.

Figure 3. (a) N_2O and (b) CH_4 fluxes vs soil WFPS from clay Oxisol (circles) and sandy loam Ultisol (triangles) soils from undisturbed sites in the Tapajós National Forest.

In the undisturbed forest N_2O flux responded significantly to WFPS (Figure 3a). For the clay Oxisol, the seasonal pattern of N_2O flux was repeated over 2 yr with clear peaks during the wet season when fluxes averaged $12.9 \text{ ng N cm}^{-2} \text{ h}^{-1}$ and troughs in the dry season when fluxes averaged $1.9 \text{ ng N cm}^{-2} \text{ h}^{-1}$ (Figure 2a; Table 1). The seasonal pattern on the sandy loam Ultisol was similar although muted with average N_2O fluxes for wet and dry seasons of 2.1 and 1.1 ng N cm^{-2}

Table 1. Seasonal and annual estimates of average trace gas fluxes (standard error (SE)) in undisturbed forest sites for (a) clay Oxisol and (b) sandy loam Ultisol. We only sampled CO₂ and NO fluxes in the dry season of 2000 so no annual estimate is given for those gases in that year. Annual fluxes are estimated as the average of wet- and dry-season fluxes. Error estimates for annual fluxes are propagated according to Equation (4). Sampling dates for 2002 are not included in the annual averages.

Year	Season	N ₂ O (SE)	NO (SE)	CH ₄ (SE)	CO ₂ (SE)
		ng N cm ⁻² h ⁻¹	ng N cm ⁻² h ⁻¹	mg CH ₄ m ⁻² day ⁻¹	μmol m ⁻² s ⁻¹
Clay Oxisol					
2000	Wet	13.0 (0.9)	na	0.3 (0.2)	na
2000	Dry	2.7 (1.0)	12.5 (3.1)	-1.0 (0.3)	4.3 (0.8)
2000	Annual	7.9 (0.7)	na	-0.3 (0.2)	na
2001	Wet	12.8 (1.2)	7.7 (3.4)	0.6 (1.5)	4.2 (0.6)
2001	Dry	1.2 (0.3)	10.4 (4.4)	-0.8 (0.8)	3.0 (0.5)
2001	Annual	7.0 (0.6)	9.0 (2.8)	-0.1 (0.9)	3.6 (0.4)
Sandy loam Ultisol					
2000	Wet	2.3 (0.2)	na	-0.7 (0.3)	na
2000	Dry	1.0 (0.1)	9.4 (1.1)	-1.4 (0.4)	4.9 (0.5)
2000	Annual	1.7 (0.1)	na	-1.0 (0.2)	na
2001	Wet	2.0 (0.4)	2.3 (1.3)	-1.2 (0.3)	6.2 (2.2)
2001	Dry	1.2 (0.4)	15.3 (9.9)	-0.6 (0.6)	3.6 (0.5)
2001	Annual	1.6 (0.3)	8.8 (5.0)	-0.9 (0.3)	4.9 (1.1)

h⁻¹, respectively (Table 1). The N₂O flux was significantly different (ANOVA, $p < 0.0001$) among season and soil type although there was also a significant season by soil interaction. This interaction is evident by inspection of Figure 2a; N₂O fluxes are greater on clay versus sand during the wet season while during the dry season they fall to similarly low levels.

Sampling for NO flux in the undisturbed forest was limited by instrument availability prior to October 2000 and by problems of instrument reliability thereafter. We report soil-atmosphere NO fluxes for only 10 and 8 sampling dates on the Oxisol and Ultisol, respectively (Figure 2c). We found no significant effect of either soil type or season on NO flux. The overall average NO flux for 2001 was 8.9 ng N cm⁻² h⁻¹ (Table 1).

Soil-atmosphere exchange of CH₄ included both net negative fluxes (soil consumption of atmospheric methane) and net positive fluxes (soil emission of methane) in both the wet and dry seasons regardless of soil type. There was a trend of decreasing CH₄ fluxes with decreasing WFPS, but the correlation was weak and insignificant (Figure 3b) regardless of soil type. Both seasonal and soil effects were significant in the analysis of variance ($p < 0.05$) and there was no significant interaction. On the clay Oxisol, in the wet season methane production dominated consumption, and the average CH₄ flux combining 2000 and 2001 was 0.5 mg CH₄ m⁻² day⁻¹ (Table 1). In contrast, in the dry season on the clay Oxisol, consumption dominated and the average flux was -0.9 mg CH₄ m⁻² day⁻¹ over those two years. Methane consumption always dominated over production on the sandy loam Ultisol. Compared with the Oxisol, methane flux was significantly more negative on

the sandy loam Ultisol with wet- and dry-season averages of -0.9 and -1.0 mg $\text{CH}_4 \text{ m}^{-2} \text{ day}^{-1}$ combining 2000 and 2001 (Table 1).

Soil-atmosphere CO_2 flux averaged $4.1 (\pm 0.3) \mu\text{mol m}^{-2} \text{ s}^{-1}$ for all measurements (unweighted) in undisturbed forest (Table 1). We found no significant effect of either soil type or season on CO_2 flux. Although not significant, there is a noticeable trend of diminishing CO_2 flux and diminishing soil moisture during the dry season (July through December) of 2001 (Figures 2d and 2e).

3.2. Effects of moisture and temperature on trace gas fluxes

In the undisturbed forest, soil WFPS had a significant influence on N_2O flux (Figure 3). There was no significant correlation between CO_2 , CH_4 , or NO and soil WFPS. Daily average soil moisture was significantly ($r^2 = 0.37$, $p < 0.001$) inversely correlated with daily average soil temperature (not shown) although the daily range of temperature was very limited, 23.3° to 27.6°C . The inverse correlation of moisture and temperature results in a weak, although significant, negative correlation of N_2O flux with soil temperature ($r^2 = 0.15$, $p < 0.01$).

3.3. Trace gas fluxes in logged forest

The seasonal patterns of N_2O and CH_4 flux following logging are shown in Figure 4 for the focal site on clay Oxisol sampled in 2000. For N_2O the pattern of high fluxes in the wet season followed by low fluxes in the dry season (Figure 4a) resembled the pattern for a similar undisturbed forest site on clay Oxisol (Figure 2a). Skid trails, gaps, and forest matrix all followed this pattern. In contrast, N_2O fluxes for the logging decks showed an inverted pattern with the greatest soil to atmosphere fluxes during the dry season. Annual average N_2O fluxes ranged from 7.5 to $14.7 \text{ ng N cm}^{-2} \text{ h}^{-1}$ across the various strata (damage classes) (Table 2). Analysis of variance on log-transformed N_2O flux data showed no significant difference among logging strata. There was a significant ($p < 0.001$) season by stratum interaction because of the inverted seasonal trends for N_2O fluxes (greater in the dry season) from the decks discussed below.

For CH_4 at the focal logging site in 2000, gap and forest matrix strata had annual fluxes (-0.7 to $4.4 \text{ mg CH}_4 \text{ m}^{-2} \text{ day}^{-1}$) similar to or slightly greater than the forest matrix (Table 2). Logging had a significant effect on CH_4 flux (ANOVA, $p < 0.01$) because emissions of CH_4 were extremely high for the heavily compacted logging decks where water frequently ponded over portions of the surface during the wet season. Dry-season emissions on log decks were dominated by a single sampling date (1 August 2000). Excluding this date, the dry-season average ($\pm$ standard error) would be only $0.6 (\pm 0.2) \text{ mg CH}_4 \text{ m}^{-2} \text{ day}^{-1}$.

We collected data for soil-atmosphere fluxes of NO and CO_2 for our focal site on only two dates in the dry season of 2000 (Table 2). Dry-season NO flux from log decks was significantly greater than NO fluxes from other logging strata (ANOVA, $p < 0.05$). There were no significant differences among CO_2 fluxes for the different logging strata.

Additional fluxes measured in other logged forests on clay Oxisol during 2000 confirm the patterns found at our focal site (Table 3). Differences in soil-atmosphere fluxes of N_2O and CO_2 across logging damage strata were minor.

Figure 4. Seasonal patterns of soil-atmosphere fluxes of N_2O and CH_4 in the focal study site logged in 1999 and sampled in 2000. Data are shown from four strata indicating decreasing levels of damage: decks (open squares), skids (filled diamonds), gaps (filled circles), and forest matrix (filled triangles). Error bars represent standard errors of the mean for individual sampling dates.

There was a tendency toward greater NO fluxes from skids and decks, but sampling was unbalanced. As was the case for our focal site in 2000, log decks had greatly elevated CH_4 emissions during the wet season. Skid trails had somewhat elevated CH_4 emissions compared to gaps and the background forest matrix.

Soil-atmosphere fluxes of CH_4 , CO_2 , N_2O , and NO from Ultisol sites logged in

Table 2. Seasonal and annual estimates of average trace gas fluxes (standard error) in the focal logged forest sites (deck 3) for clay Oxisol logged in 1999 and sampled in 2000. Annual fluxes are estimated as the average of wet- and dry-season fluxes. Error estimates for annual fluxes are propagated according to Equation (4).

	N_2O (ng N cm ⁻² h ⁻¹)			CH_4 (mg CH ₄ m ⁻² day ⁻¹)		
	Wet	Dry	Annual	Wet	Dry	Annual
Forest	13.7 (3.1)	1.3 (0.1)	7.5 (1.6)	-0.5 (0.4)	-0.8 (0.3)	-0.7 (0.2)
Gap	21.5 (5.7)	3.3 (1.7)	12.4 (3.0)	1.3 (0.5)	0.4 (0.4)	0.8 (0.3)
Skid	24.5 (3.0)	4.1 (2.3)	14.3 (1.9)	7.1 (5.9)	1.8 (1.0)	4.4 (3.0)
Deck	8.6 (2.3)	18.2 (7.0)	13.3 (3.7)	211 (159)	852 (823)	531 (419)

September 2000 and measured from February 2001 through January 2002 are displayed in Table 4. Similar to observations made during 2000, the most salient result is the large increase of CH_4 emission from log decks (annual average emission of $98 \text{ mg CH}_4 \text{ m}^{-2} \text{ day}^{-1}$) compared to other damage strata (0.0 to $2.4 \text{ mg CH}_4 \text{ m}^{-2} \text{ day}^{-1}$). Analysis of variance of log-transformed CH_4 fluxes showed a significant effect of stratum, season, as well as a season by stratum interaction ($p < 0.001$). The interaction results from very high emissions of CH_4 from ponded decks during the wet season compared to low emissions during the dry season. Other strata have a muted seasonal signal by comparison (Table 4). In contrast to CH_4 , logging had no significant effect on soil-atmosphere exchange of CO_2 .

The behavior of soil-atmosphere N_2O and NO fluxes from the logged Ultisol sites were inverted both with respect to season and with respect to logging damage. Greatest N_2O fluxes were observed during the wet season and in the more compacted soils of log decks and skid trails (Table 4). The greatest NO fluxes were found during the dry season from the forest matrix and logging gap soils that did not suffer compaction. In both cases analysis of variance on log-transformed data showed a significant effect of season and logging stratum (N_2O and NO , $p < 0.001$).

3.4. Comparison of fluxes in undisturbed forest versus the background matrix in logged sites

We compared undisturbed forest fluxes of N_2O and CH_4 for the clay Oxisol background forest site and the focal logging site on the same soil type during 2000 using ANOVA. Average daily fluxes were taken as replicates. Both N_2O and CH_4 fluxes were significantly greater in the wet season versus the dry season. However, there was no significant difference by site. Undisturbed forest and the forest matrix in the logged site have similar fluxes. We only sampled NO and CO_2 in the dry season of 2000. We found no significant differences in fluxes for these gases between the undisturbed forest and matrix forest in logged sites.

We performed the same analysis on the Ultisol sites measured in 2001 with a similar outcome for all gases but N_2O . In the case of N_2O flux, the ANOVA on log-transformed data shows a significant ($p < 0.001$) effect of season as expected but unexpectedly a significantly greater N_2O flux from the forest matrix within the logging site than for the background forest site. In the case of CH_4 , neither site nor season had a significant effect. For log-transformed values of NO flux, there was a significant ($p < 0.05$) seasonal effect with greater fluxes in the dry season but no effect of site. The CO_2 fluxes were significantly greater ($p < 0.05$) in the wet season, but again there was no effect of site. Overall, with the exception of N_2O on the Ultisols in 2001 we could find no significant effect of site on trace gas flux when comparing the background forest with the relatively undisturbed forest matrix within the logging sites.

3.5. Ground damage resulting from logging

Approximately 10 ha (10%) of the ground area in block 3 logged in 1999 suffered mechanical disturbance and compaction due to the passage of skidders, loaders, crawler tractors, and trucks. About 1.3% of the area was covered by roads, 7.7%

Table 3. Annual estimates of trace gas fluxes (standard error) in nonfocal logged forest sites logged in 1999 and sampled in 2000 (Oxisol). When only one season was sampled, no annual estimate is given for those gases in that year. Annual fluxes are estimated as the average of wet- and dry-season fluxes. Error estimates for annual fluxes are propagated according to Equation (4).

	N ₂ O (ng N cm ⁻² h ⁻¹)			NO (ng N cm ⁻² h ⁻¹)			CH ₄ (mg m ⁻² day ⁻¹)			CO ₂ (μmol m ⁻² s ⁻¹)

Table 5. Average ($\pm$ SE) bulk density for surface soil (0–10 cm) in management blocks 3 (logged in 1999) and 9 (logged in 2000) in four disturbance classes ($n = 8$ per class).

Block	Soil	Deck	Skid trail	Clearing	Forest
		Mg m ⁻³			
3	Oxisol	1.28 (0.05)	1.09 (0.07)	1.07 (0.06)	1.04 (0.04)
9	Ultisol	1.26 (0.07)	1.04 (0.05)	1.00 (0.05)	1.02 (0.04)

by skids, and 0.8% by decks. The majority (78%) of the mechanical disturbance was caused by skidding along the dendritic pattern of planned trails (Figure 1). Mechanical disturbance led to significantly increased bulk density (ANOVA, $p < 0.01$) especially in the soils on logging decks on both the clay Oxisol and sandy loam Ultisol (Table 5).

3.6. Excess trace gas fluxes resulting from logging

The excess soil–atmosphere fluxes resulting from logging are presented in Table 6. We performed the calculation only when a full year of data was available so we concentrated on the focal site on the Oxisol (Table 2) and the combined sampling on the Ultisol (Table 4). The excess flux was quite sensitive to our assumption of background. We calculated excess fluxes using either the undisturbed forest fluxes (Table 1) for the appropriate year and soil type or the forest matrix within the logging site as background values ($f_{\text{background}}$). Where the undisturbed forest is considered the background, we also considered the forest matrix within the logging sites as part of the treatment effect although with only one exception: there was no statistically significant difference between the fluxes from the forest matrix in the logged sites and the fluxes measured in undisturbed forest. For N₂O flux from the Ultisol site studied in 2001, the forest matrix flux at the logged site was 5.0 (± 0.8) ng N cm⁻² h⁻¹. This was significantly greater than the flux in the undisturbed forest, only 1.6 (± 0.3) during the same period. When we used the undisturbed forest for the background value, then the excess flux is 7.9 kg N₂O ha⁻¹ yr⁻¹. However, if we considered the forest matrix within the logging site to be the background then the excess flux diminished to only 3.2 kg N₂O ha⁻¹ yr⁻¹ (Table 6b).

4. Discussion

4.1. Trace gas fluxes in undisturbed forest

Soil–atmosphere fluxes of N₂O from the undisturbed forest site on the clay Oxisol, 6.9 and 6.1 kg N ha⁻¹ yr⁻¹ for 2000 and 2001, were among the highest fluxes measured for any lowland old-growth tropical moist forest ecosystem. On the other hand, the fluxes for the sandy loam Ultisol, 1.5 and 1.4 kg N ha⁻¹ yr⁻¹ for 2000 and 2001, fell toward the lower end of values recently compiled by Breuer et al. (Breuer et al. 2000). The N₂O fluxes from the clay Oxisol were especially high when compared to measured fluxes on similar clay-textured Oxisols in the municipalities of Manaus and Paragominas, Brazil, where annual fluxes ranged from 1.9 to 2.4 kg N ha⁻¹ yr⁻¹ (Luizão et al. 1989; Verchot et al. 1999). The N₂O

Table 6a. Average annual fluxes (SE) and calculated excess fluxes (propagated error) as in Equation (3) for the Oxisol site harvested in 1999 and measured in 2000. The CO₂ equivalents (shown in boldface) of the excess fluxes were calculated using the 2001 IPCC GWP for the greenhouse gases N₂O and CH₄ (Ramaswamy et al. 2001).

Oxisol	Area (A _i /A _T)	N ₂ O kg N ₂ O ha ⁻¹ yr ⁻¹	NO kg NO ha ⁻¹ yr ⁻¹	CH ₄ kg CH ₄ ha ⁻¹ yr ⁻¹	CO ₂ kg CO ₂ ha ⁻¹ yr ⁻¹
Background forest		10.9 (1.0)	—	-1.1 (0.7)	
Forest matrix	0.475	10.4 (2.2)	—	-2.6 (0.7)	—
Gap	0.440	17.1 (4.1)	—	2.9 (1.1)	—
Skid trail	0.077	19.7 (2.6)	—	16.1 (11.0)	—
Deck	0.008	18.4 (5.1)	—	1940 (1530)	—
Excess vs matrix		3.8 (2.2)	—	19.4 (12.3)	—
Excess vs background		3.2 (2.3)	—	6.8 (12.3)	—
CO₂ equivalent vs matrix		1110 (640)		450 (280)	
CO₂ equivalent vs background		950 (690)	—	160 (280)	—

emissions from the sandy loam Ultisols were similar to emissions from forests on Ultisol of 1.9 kg N ha⁻¹ yr⁻¹ in the state of Rondonia, Brazil. On both soils, interannual variability was strikingly small considering the episodic nature of N₂O fluxes (Crill et al. 2000). In comparison, annual estimates for two 1-yr periods of N₂O fluxes for a wet tropical forest site in Queensland, Australia, using automated chambers measured about four times daily, varied by a factor of 7 (Kiese et al. 2003).

Annual N₂O fluxes from the undisturbed forest sites were 4 times greater on the clay Oxisol soil compared to the sandy loam Ultisol. This result conforms to the expectations of the hole-in-the-pipe (HIP) model (Firestone and Davidson 1989; Davidson et al. 2000). According to HIP, nitrogen oxide fluxes are controlled at a first level by the rate of nitrogen cycling through the soil system. At a second level in the HIP model, nitrogen oxide fluxes are controlled by soil moisture content that controls the diffusion of oxygen and other gases into the soil. Both levels of control favor greater N₂O emissions from the clay Oxisol as compared to the sandy loam Ultisol. On the first level, the net nitrification rate, an index of nitrogen cycling, was 3 times higher on the clay Oxisol than on the sandy loam Ultisol (Silver et al. 2000). On the second level, the clay Oxisol had greater WFPS than the sandy loam Ultisol (Figure 3). Additionally, the response of N₂O fluxes to increases in WFPS

Table 6b. Similar to Table 6a but for the Ultisol site harvested in 2000 and measured in 2001.

Ultisol	Area (A _i /A _T)	N ₂ O kg N ₂ O ha ⁻¹ yr ⁻¹	NO kg NO ha ⁻¹ yr ⁻¹	CH ₄ kg CH ₄ ha ⁻¹ yr ⁻¹	CO ₂ kg CO ₂ ha ⁻¹ yr ⁻¹
Background forest		2.2 (1.0)	16.5 (9.4)	-3.3 (1.1)	67 900 (15 200)
Forest matrix	0.475	6.9 (1.1)	49.1 (27.8)	8.8 (8.0)	63 800 (4200)
Gap	0.440	12.3 (3.5)	84.6 (50.9)	0.0 (1.5)	70 700 (5500)
Skid trail	0.077	14.9 (2.9)	8.1 (1.3)	5.8 (2.6)	70 700 (8300)
Deck	0.008	37.5 (14.4)	13.3 (3.9)	357.7 (149.7)	58 200 (5500)
Excess vs matrix		3.2 (1.6)	12.2 (26.7)	-1.3 (4.4)	3540 (3340)
Excess vs background		7.9 (1.7)	44.7 (27.7)	10.8 (4.2)	-620 (15 500)
CO₂ equivalent vs matrix		960 (490)	—	-30 (100)	3540 (3340)
CO₂ equivalent vs background		2340 (500)	—	250 (100)	-620 (15 500)

was more pronounced. At high moisture contents, denitrification typically dominates tropical forest soil N_2O production (Parsons et al. 1993). Potential denitrification was 4 times greater on the clay Oxisol than on the sandy loam Ultisol (Silver et al. 2000).

The seasonal pattern of soil–atmosphere fluxes of NO is inverted compared to N_2O . Nitric oxide is easily consumed in soil compared to N_2O (Galbally and Johansson 1989; Bollmann and Conrad 1998); therefore, NO emission depends much more on gaseous diffusivity in soil. When soils were relatively dry and diffusivity was high, NO emissions were greater than when soils were wet. Emissions from the Oxisol and Ultisol were nearly identical. This observation does not correspond to the first-order nitrogen control in the HIP model possibly because consumption processes dominate over production in the control of emissions.

In comparison to three other Amazon forest sites, soil emissions of NO from our sites at the TNF were very large. We found annual emissions of NO from the sandy loam Ultisol and clay Oxisol of 7.7 and 7.9 kg N ha^{−1} yr^{−1} compared to a range of 1.4 to 1.7 kg N ha^{−1} yr^{−1} for three other forested sites in the Amazon where seasonal series of measurements are available (Neill et al. 2005). Part of the discrepancy across sites may be methodological. All of our NO flux measurements were calibrated in the field. In contrast, the other measurements in the Amazon, although made using detectors manufactured by the same vendor, were calibrated under laboratory conditions only before and after field measurements. We have found that field calibrations can vary from laboratory calibrations on the same day by as much as 60% (Varner et al. 2003). This methodological uncertainty probably does not account entirely for the discrepancy between our measurements and those made by others. We note that the higher NO fluxes at our sites compared to others are consistent with similarly higher N_2O fluxes compared to other sites in the Amazon region.

Soil–atmosphere CH_4 fluxes were similar to other sites in the Amazon region. Verchot et al. (Verchot et al. 1999) found annual methane fluxes of -0.6 mg CH_4 m^{−2} day^{−1} for a forested site in Paragominas on a clay-rich Oxisol and Steudler et al. (Steudler et al. 1996) found annual fluxes averaging from -1.3 to -2.1 mg CH_4 m^{−2} day^{−1} for an Ultisol at Fazenda Nova Vida in Rondonia, Brazil. The CH_4 flux followed seasonal patterns of soil moisture with greatest CH_4 consumption during the dry season and moderate production in the wet season similar to other tropical forest sites (Keller and Reiners 1994).

The annual estimates of soil CO_2 efflux from the undisturbed forest Oxisol and Ultisol sites for 2001 were about 14 (± 2) and 19 (± 4) Mg C ha^{−1} yr^{−1}. In comparison, we found that soil CO_2 efflux summed to about 10 Mg C ha^{−1} yr^{−1} for a site on the same Oxisol about 20 km away by using an automated system that measured eight chambers about 5 times daily over two years beginning in April 2001 (Saleska et al. 2003). A difference of 4 Mg C ha^{−1} yr^{−1} is quite large in terms of net ecosystem carbon flux. We made our measurements in the daytime imparting a bias toward greater fluxes associated with higher soil temperatures but this effect is slight in the well-shaded tropical forest soils (R. Varner, 2005, personal communication). The limited number of manual CO_2 flux measurements at our undisturbed forest Oxisol site and the natural variability of soil–atmosphere flux probably accounts for the observed differences.

Recently, two groups have found that N_2O and CO_2 fluxes correlated in tropical

forest soils (Breuer et al. 2000; Garcia-Montiel et al. 2002; Garcia-Montiel et al. 2004). In contrast, we found a significant correlation between N_2O and CO_2 fluxes only under very limited conditions, specifically for the sandy loam soil during the dry season. In that case, the slope of the line relating N_2O and CO_2 is far shallower than found by Garcia-Montiel et al. (Garcia-Montiel et al. 2002) (Figure 5). When wet-season data were considered, the correlation between N_2O and CO_2 fluxes disappeared. In tropical forest soils, the N_2O source has a strong denitrification component (e.g., Parsons et al. 1993; Breuer et al. 2000; Garcia-Montiel et al. 2001). Denitrification is an anaerobic process whereas soil CO_2 emissions are promoted by well-aerated moist conditions (Linn and Doran 1984). Garcia-Montiel et al. (Garcia-Montiel et al. 2004) have used the correlation between N_2O and CO_2 fluxes for estimation of N_2O emissions across the Amazon region. This approach ignores denitrification as an important source of N_2O . It fails for our study sites and we believe it is inappropriate for extrapolation across the Amazon region where anaerobic processes exercise a strong control over N_2O production (Verchot et al. 1999; Garcia-Montiel et al. 2001).

4.2. The effect of logging on trace gas fluxes

Passage of heavy machinery over the soil affects about 10% of the logged area in these RIL managements. Under CL nearly twice as much area would be affected (Pereira et al. 2002). Mechanical disturbance leads to soil compaction. On log decks, the compaction is severe and a 20% increase in soil bulk density was measured (Table 6). In contrast, there was only moderate compaction on skid trails that was more notable in the clay soils. Soil compaction led to impeded drainage that was especially prominent on the log decks that ponded, at least in part, early during the wet season and did not drain entirely until one to two months after the dry season began. The wet conditions of the decks even in the dry season affects dry-season gas fluxes as we discuss below.

Soil compaction impedes the drainage of water through the soil and results in a reduction of diffusive gas exchange between the soil and the overlying atmosphere. Reduced penetration of oxygen into the soil greatly modifies soil biogeochemical processes. This is illustrated by the shift from a dominance of the oxidative process of CH_4 consumption in the undisturbed forest sites to large production of CH_4 on log decks through anaerobic respiration. Production of CH_4 from log decks at rates comparable to tropical wetland environments (Crill et al. 1988) was the most notable and consistent change caused by logging.

Shifts in the biogeochemical condition of the soil, especially with regard to oxidation and reduction, were also evident in the seasonal patterns of trace gas flux (Figure 4). Nitrous oxide production and emission are maximized at intermediate levels of soil oxygenation between fully oxidized and fully reduced (Linn and Doran 1984; Keller et al. 1986; Davidson et al. 2000). We found that in the forest matrix, skid trail, and gap logging strata, N_2O emission peaked during the wet season while on the log decks, N_2O emission peaked during the dry season. During the wet season log decks were covered with water and the saturated soil was sufficiently reduced to produce large quantities of CH_4 . Under those strongly reducing conditions, N_2O would have been consumed by soil denitrifying organisms. Emissions of NO are favored by drier conditions than emissions of N_2O .

Figure 5. Flux of N_2O vs CO_2 for (top) dry season and (bottom) all data from undisturbed forest sites on both clay Oxisol and sandy loam Ultisol at the Tapajos National Forest. The solid line marks the regression determined for N_2O vs CO_2 for sites in Rondonia (Garcia-Montiel et al. 2002). The dashed and dotted lines show regressions for N_2O vs CO_2 for dry-season data only from the Tapajos National Forest. Error bars represent standard errors of the mean for individual sampling dates.

(Bollmann and Conrad 1998). In general, the more reducing environments had smaller NO emissions compared to the more oxidizing environments and NO emissions in the dry season exceeded NO emissions during the wet season.

Logging results in a large nearly instantaneous input of organic matter both above- and belowground. Fresh leaves and roots added to the forest floor cause large pulses in nutrient availability in tropical forests (Scatena et al. 1996). Loss of nutrient uptake by roots added to the forest floor causes greater leaching (Brouwer 1996). Nitrate losses from selective harvest in Guyana varied in proportion to the area of soil disturbance surrounding harvested trees. Leaching of nitrate in large harvest gaps was exceptionally high, amounting to 19 g N m^{-2} during the first three years following harvest on podsoles (Brouwer 1996). Large-scale root disturbance in trenching experiments has also been shown to approximately double the emission of N_2O during 10 weeks following disturbance (Varner et al. 2003). Root mortality following logging disturbance may contribute to the increased emissions of nitrogen oxides.

4.3. Possible regional effects of logging on trace gas fluxes

Logging has become a large-scale land use in the Brazilian Amazon affecting at least $10\,000 \text{ km}^2$ of forest per year (Nepstad et al. 1999) so we evaluate the possibility that regionally significant emissions of trace gases may result from these practices. The effect of logging on soil–atmosphere trace gas flux was often difficult to distinguish statistically because of the high temporal and spatial variability in trace gas fluxes. Nonetheless, even where our experimental design did not reveal significant effects, we used our available measurement to calculate excess trace gas fluxes resulting from logging and we propagated errors for those calculations to indicate the large degree of uncertainty. As noted above, these results can be quite sensitive to the assumption of the background condition.

For the clay Oxisol site, we found that the excess N_2O flux was about 30% of the background emission regardless of our assumptions. For the sandy loam Ultisol, the excess flux was of similar magnitude when the forest matrix was considered as background but twice as large when we considered the undisturbed forest site as background. If we consider that logging affects about $1.5 \times 10^6 \text{ ha yr}^{-1}$ in the Brazilian Amazon and we select our largest excess value for N_2O ($7.9 \text{ kg N}_2\text{O ha}^{-1} \text{ yr}^{-1}$), then we calculate that the effect of a single year's logging disturbance in Brazil could add up to $7.5 \times 10^{-3} \text{ Tg N}_2\text{O N yr}^{-1}$ to the troposphere. This effect is at most about 1% of the estimated emissions of N_2O , $0.8 \text{ Tg N}_2\text{O N yr}^{-1}$ from the Brazilian Amazon region (Melillo et al. 2001). Ground and canopy disturbance at the RIL sites that we studied is about half that of the far more common CL harvest management. Doubling the maximum excess flux that we measured for N_2O to account for greater ground disturbance in CL would lead to an effect less than 2% of the estimated annual emissions of N_2O for the Brazilian Amazon. However, increased fluxes may last more than one year as we will discuss below.

Our data for NO are limited and highly variable. Regardless of the selection of background flux, there was a notable positive enhancement of flux resulting from logging at the Ultisol site. Compared to the long-lived greenhouse gases such as N_2O , it is more difficult to put the increased NO flux into a regional perspective. Increases in regional NO emissions in the Amazon would likely increase the

regional production of the oxidant and greenhouse gas ozone (O_3) (Keller et al. 1991; Andreae et al. 2002). However, once released from the soil NO oxidizes to form NO_2 that is readily consumed in the forest canopy (Rummel et al. 2002). Opening the canopy through logging may increase canopy ventilation and trace gas exchange, but this has not been quantified. Assuming this process led to greater NO release, we would expect logging to contribute to enhanced O_3 production regionally (Keller et al. 1991).

The increase in soil–atmosphere methane emission from log decks was an unambiguous effect of logging. Depending upon our assumptions, logging had anything from a negligible effect on CH_4 emissions to a considerable augmentation of emissions. The forest matrix in the logging on the Ultisol had a small net CH_4 emission on an annual basis. This net emission is highly uncertain but use of this value as background in Eq. (1) tends to minimize the effect of high fluxes from the log decks on the estimate of excess flux. Using the maximum excess flux of $446 (\pm 282) \text{ kg } CH_4 \text{ ha}^{-1} \text{ yr}^{-1}$ and $1.5 \times 10^6 \text{ ha yr}^{-1}$ of logging the Brazilian Amazon, we calculate that the effect of a single year's logging disturbance in Brazil could add up to $0.7 (\pm 0.4) \text{ Tg } CH_4 \text{ yr}^{-1}$ to the troposphere. Given that the annual production of methane from the full Amazon basin below 500-m elevation is about $29 \text{ Tg } CH_4$ (Melack et al. 2004), the potential importance of logging disturbance should not be overlooked. Steudler et al. (Steudler et al. 1996) estimated that the effect of forest to pasture conversion including cattle CH_4 emissions accounted for about $2.5 \text{ Tg } CH_4 \text{ yr}^{-1}$ in the Brazilian Amazon in 1990. Logging decks tend to occupy about twice the area under CL management compared to RIL, so our estimates could be as much as a factor of 2 too low.

The importance of logging as an influence on regional trace gas budgets depends on the spatial variability of the response of trace gas emissions to logging. Our studies were limited to one forest with one management approach, although we did study two contrasting soil types that are common in the Amazon region. No single site can be considered representative and we caution that our efforts at extrapolation to the region are mainly to illustrate the possibilities. Definitive conclusions require further studies at other sites.

Our studies of logging effects on trace gas emissions only cover the first year following logging disturbance. Would the perturbations to trace gas emissions occur for longer time periods? If so, then logging would have a more significant regional impact on trace gas budgets. For the nitrogen oxides, both changes in nutrient cycling as well as changes in soil physical properties may have regulated the observed changes in emissions. Excess nitrogen availability following disturbance would probably last at most a few years as found in the case of forest-to-pasture conversion in the Amazon (Neill et al. 1995). Forest-to-pasture conversion caused increased N_2O emissions in the Amazon that lasted about three years (Melillo et al. 2001) although the increase of N_2O flux following disturbance lasted up to a decade in Costa Rica (Keller et al. 1993). If we assume that excess N_2O fluxes following logging persist for three years at the levels that we observed then logging may augment N_2O emissions by as much as 5%–6% over current levels on a regional basis.

In the case of CH_4 , soil compaction is the main driver of excess fluxes. Changes in soil bulk density in skid trails have been shown to last as long as 16 yr by investigators working on the Oxisol at the Tapajos National Forest (McNabb et al.

1997). Although McNabb et al. (McNabb et al. 1997) did not present data from old logging decks, we also would expect them to remain compact for a long time. However, we have observed that within about three years following logging, log decks are covered by trees and unless these trees are adapted to long periods of root anaerobiosis, it is likely that soil aeration improves with time and that the potential for methane emission on log decks decreases with time. Overall, we would expect compaction-related effects on CH_4 flux to diminish with time. Again if we assume a 3-yr time horizon for increased fluxes, it is possible that logging could have an effect on CH_4 budgets similar in magnitude ($\sim 2 \text{ Tg CH}_4 \text{ yr}^{-1}$) to the net effect of forest-to-pasture conversion.

4.4. Trace gas emissions and carbon budgets from logging in the Amazon

To put the trace gas emissions into perspective, we evaluated them compared to CO_2 emissions using the concept of global warming potential (GWP). We selected a 100-yr integration time for GWP following the recent recommendations of the Intergovernmental Panel on Climate Change (IPCC; Ramaswamy et al. 2001). In a short-term perspective, a great deal of carbon is effectively committed to release to the atmosphere by logging. We found that even using less destructive RIL techniques at the TNF logging removed the equivalent of $41 \text{ Mg CO}_2 \text{ ha}^{-1}$ in harvested wood and $47 \text{ Mg CO}_2 \text{ ha}^{-1}$ as necromass (Keller et al. 2004a). If we compare the CO_2 equivalents of soil emissions of N_2O , CH_4 , and CO_2 (Table 6) to these instantaneous values, the trace gas effects appear to be small.

There are few carbon budgets for logged tropical forest sites and most consider the immediate carbon loss following logging (e.g., Pinard and Putz 1996; Gerwing 2002). We made preliminary estimates for the carbon balance of logging at the Tapajos National Forest using field measurements of damage and simple models of decay, regrowth, and off-site carbon loss to predict carbon budgets following logging (Keller et al. 2004b). To account for regrowth following logging, we integrated fluxes over 30 yr assuming single harvesting entries, a new harvested area each year, and simulated regrowth following logging. For a 30-yr integration under RIL management we predicted a loss of $1500 \text{ kg CO}_2 \text{ ha}^{-1} \text{ yr}^{-1}$. It is difficult to compare this loss to the excess trace gas flux following logging because we do not have an estimate for a 30-yr period. If we assume that excess fluxes of N_2O , CH_4 , and CO_2 endure for three years, that is equivalent to assuming that 10% of the area has an excess flux. Adding the maximum and minimum excess fluxes as CO_2 equivalent across both soil types for N_2O , CH_4 , and CO_2 from Table 6, summing their errors in quadrature and adjusting for 10% of the area, we get a wide range of outcomes between $633 (\pm 338)$ and $30 (\pm 1559) \text{ kg CO}_2 \text{ ha}^{-1} \text{ yr}^{-1}$. These effects range from trivial to more than one-third of the effect of carbon loss alone. Effects of both trace gases and carbon would be larger for CL.

5. Conclusions

Logging causes notable changes to trace gas emissions at a local level. Extrapolation to a region as large and diverse in forest types, soils, and management conditions as the Amazon region of Brazil is impossible from a single site. If

similar perturbations happen at other sites, and if these perturbations last for several years, then regional emissions of N_2O and CH_4 from the Brazilian Amazon could be increased by 5%–10%. The effect of these emissions in terms of GWP may be as much as one-third as large as the estimated effect of carbon loss from vegetation alone. We note that reduced impact logging (RIL) practices that control harvest damage, especially those that minimize the area of mechanical soil disturbance, will also mitigate excess N_2O and CH_4 fluxes related to logging.

Acknowledgments. We thank two anonymous reviewers for their helpful comments. Michael Palace, Maria Hunter, and Lorena Brewster provided valuable support in data processing, preparation of the figures, and formatting of the bibliography. Barbara Wick, Kadson Oliveira, Cleuton Pereira, and Francisco Alves Freitas Neto assisted with the field collections and laboratory work. We are grateful to the Brazilian Ministry of Science and Technology (MCT) for their leadership of the Large-Scale Biosphere–Atmosphere Experiment in Amazonia (LBA) and to Brazil’s Center for Weather Prediction and Climate Studies (CPTEC) and Brazil’s National Institute for Amazon Research (INPA) for their management of that program. Johan Zweede and the staff of the Fundação Floresta Tropical provided logistical and managerial support for our field studies. We are grateful to NASA (NCC5-225, NCC5-357, and NAG5-8709), the U.S. Forest Service, and USAID for financial support.
