ABSTRACT

We report the results of recent calibration data analysis of a prototype scintillating fiber tracking detector system designed to perform imaging, spectroscopy and particle identification on 20 to 250 MeV neutrons and protons. We present the neutron imaging concept and briefly review the detection principle and the prototype description. The prototype detector system records ionization track data on an event-by-event basis allowing event selection criteria to be used in the off-line analysis. Images of acrylic phantoms from the analysis of recent proton beam calibrations (14 to 65 MeV range) are presented as demonstrations of the particle identification, imaging and energy measurement capabilities. The measured position resolution is < 500 μm. The measured energy resolution (ΔE/E, FWHM) is 14.2% at 35 MeV.

The detection techniques employed can be applied to measurements in a variety of disciplines including solar and atmospheric physics, radiation therapy and nuclear materials monitoring. These applications are discussed briefly as are alternative detector configurations and future development plans.

Keywords: neutron, proton, tracking, imaging, spectroscopy, scintillating fiber, CCD, image intensifier, solar

1. INTRODUCTION AND MOTIVATION

Neutron telescopes based on double scatters are particularly effective in high background environments. The neutron telescope described here, known as SONTRAC, the SOlar Neutron TRACking telescope, is under development to study the high energy processes associated with solar flares. When high-energy charged particle reactions occur on the surface of the Sun, neutrons carry away information about the spectrum of ions that produced them and can be used as diagnostic measures of that spectrum.

A number of other applications for such a device have also been identified. In the earth’s atmosphere neutrons above 10 MeV produce so-called soft error upsets in microcircuitry and they also present a radiation health hazard for personnel at high altitudes. Neutron telescopes can accurately determine the properties of the neutron background. Neutron tracking detectors can also be employed to accurately locate nuclear materials (waste, spills).

The success of Proton radiotherapy is based on the precision with which the dose is deposited in the tumor volume. The tracking detector described here can be used to directly detect incident protons and precisely image the absorbing material to properly register a patient within the proton beam.

2. NEUTRON IMAGING CONCEPT

The detector measures the energy and direction of neutrons by detecting double neutron-proton scatters and recording images of the ionization tracks of the recoil protons in a densely packed bundle of scintillating plastic fibers stacked in orthogonal layers. The kinematics of the scatter are determined by tracking the recoil protons.

The double-scattering of a non-relativistic neutron in a solid block of plastic scintillator is illustrated in Figure 1. Neutrons interact in plastic scintillator either by elastically scattering from hydrogen (n-p) or by interacting with carbon (n-C). The n-p events are the most useful. For the non-relativistic case.

\[
\sin^2 \phi_n = \cos^2 \phi_p = \frac{E_p}{E_n + E_p} = \frac{E_p}{E_n}
\]

where \(E_n\) is the incident neutron energy; \(E_n'\) and \(E_p'\) are the scattered neutron and photon energies, respectively; \(\phi_n\) and \(\phi_p\) are the neutron and proton scatter angles, respectively. The kinematics of nonrelativistic scattering further dictate that the scattered neutron and proton momenta are perpendicular to one another.

If the incident direction of a neutron is known, then the measurement of the energy and direction of a recoil proton in a single scatter is sufficient to determine the incident neutron energy. In particular, if the incident direction is known, then \(\phi_n\) is determined and the neutron energy is

\[
E_n = \frac{E_p'}{\cos^2 \phi_p}
\]

A more general approach, however, is provided by double-scatter events (Figure 1). If both recoil protons in a double scatter event are measured, then the energy and incident direction of the neutron are uniquely determined. The angular and energy resolution depend upon the ability to precisely measure the energy and direction of the recoil protons. Double scatter events can be used to measure neutron intensity from an extended source such as the secondary neutrons produced in the atmosphere by the primary cosmic radiation. For solar neutrons, double scatter events are also preferred, because they allow for a more complete separation of the source signal from the ambient background.

3. DETECTOR CONCEPT

The tracking detector employs a closely packed bundle of square cross section plastic-scintillator fibers. The fibers are arranged in stacked planes with the fibers in each plane orthogonal to those in the planes above and below. This alternating orientation allows one to record stereoscopic images and track ionizing particles in three dimensions in the scintillating fiber bundle. We have baselined a fiber pitch of 300 \(\mu\)m, a value chosen so that a 10 MeV proton traverses several fibers before stopping. Figure 2 represents a tiny (3 mm cubic) segment of such a bundle.

The neutron angular resolution is dependent upon the ability to precisely track the recoil protons. Track imaging employs two CCD cameras, one for each set of orthogonal fiber planes. The ionization track length is a sensitive measure of the recoil proton energy. The location of the Bragg peak, which corresponds to the greater ionization at the end of the track, fixes the track direction.

Figure 2. Small segment of a fiber bundle, illustrating orthogonal scintillator fiber layers with 300 \(\mu\)m pitch.
4. PROTOTYPE DESCRIPTION

The first SONTRAC laboratory prototype is shown in Figure 4. The prototype tracker is a 10 cm long bundle of 250 μm square scintillating plastic fibers on 300 μm pitch within a 12.7 mm square envelope. It is limited to tracking in two dimensions. The specifications of its key components and the manner in which it is operated (fiber composition and pitch, photocathode and phosphor composition, self triggered image gating and acquisition scheme) have been reported.9

5. MEASUREMENTS AND ANALYSIS

5.1. Neutron detection demonstration

The SONTRAC prototype was exposed to 14 MeV neutrons at San Diego State University and to higher energy (up to 65 MeV) neutrons and to protons at the Crocker Laboratory cyclotron facility at the University of California at Davis. Figure 5 shows a raw CCD image of a neutron double interaction in the prototype fiber bundle. Two recoil proton tracks are evident from a single neutron (~65 MeV) incident from the top of the figure. Note the evidence of the Bragg peak. “Holes” in the track images represent the passage of the ionizing particles through the passive cladding and EMA materials.
5.2. Measurements with protons

A practical calibration approach involves direct irradiation of the fiber bundle with protons. Figure 6 shows the track of a ~20 MeV proton incident from the left. In this figure the intensity is averaged over each fiber and a calibration mask of the fiber bundle is superposed on the track image. Note that the track of the incident proton, unlike those from incident neutrons, starts at the edge of the bundle.

Measurements performed at the Crocker Laboratory used a variety of phantom absorbers placed between the proton beam and the tracking detector to measure and calibrate the response and to demonstrate its spectroscopic and imaging capabilities. The geometry for one such test is illustrated in Figure 7. The phantom absorber is a 24.78 mm thick acrylic block (1.18 g/cm³) with 3.88 mm deep, 2.86 mm wide slots on 6 mm centers. The slots run parallel to the scintillating fiber axis. The prototype’s scintillating fiber bundle is 12.7 mm wide (42 fibers on 0.3 mm pitch) thus spanning slightly more than two pitch lengths of the phantom pattern.

Figure 8 shows the accumulated sum of intensity per fiber for the track images of 555 selected events. Recall that data are recorded for every event permitting analysis on a variety of criteria. In this case particles scattered from nearby material in the laboratory were identified and rejected either by the oblique slope of the track image or by the point of entry into the fiber bundle. The figure illustrates the signature of two pitch cycles of the phantom slot pattern.
Figure 9 is the distribution of the computed track length of each event represented in Figure 8. The sharp peaks represent individual fibers. Two Gaussian envelopes are evident representing the two proton energies emerging from the slotted phantom.

The measured track length is 24.5 ±1.3 fibers for protons passing through the slots and 11.8 ±1.3 fibers for protons passing through the full thickness of the acrylic block. The difference of 3.8 ±0.5 mm (12.7 ±1.8 fibers) agrees with the depth of the slots in the phantom. These data agree well with simulations that include straggling (Figure 10), which predict track lengths of 25.3 ± 1.3 fibers and 11.0 ± 1.4 fibers, respectively. The measured energy resolutions (ΔE/E, FWHM) are 14.2% at 35 MeV and 16.5% at 27 MeV.
Figure 11. Relative intensity of accumulated track images (left). The proton beam was passed through a variety of acrylic phantoms (right).

Images from other runs employing other acrylic phantom geometries are shown in Figure 11. The 65.7 MeV protons pass completely through the fiber bundle with no phantom absorber present (a). Uniform proton track lengths are observed in the fiber bundle detector when a phantom of uniform thickness is placed between it and the proton beam (b). Longer proton track lengths corresponding to lower phantom density are observed when a uniform thickness phantom with a 3 mm diameter hole drilled parallel to the fiber axis is used (c). The position of the hole in the image shifts accordingly when the detector is moved 3 mm vertically (d).

6. FUTURE WORK

On-going work involves the fabrication and test of a minimally-configured three-dimensional SONTRAC science model (SM). Unlike the first SONTRAC prototype described above, the science model is based on a fiber bundle with orthogonal fiber layers (as depicted in Figure 2), thus permitting track imaging and reconstruction in 3 dimensions. The SM will employ a 5 x 5 x 5 cm scintillating plastic fiber tracking detector with appropriately sized optoelectronic components (Figure 12). The larger size of the SM fiber bundle will permit measurements at higher energies where n-C scatters occur. The goals of this science model study are to characterize the performance of the three dimensional version of SONTRAC and to refine the necessary electronics configuration and data processing algorithms for an engineering model. Calibrations are planned for both neutrons and protons at energies from 10-80 MeV, a range which covers from below the nominal threshold up to energies where neutron double scatter events are no longer contained within the SM fiber block.

The small (300μm) fiber size of the SONTRAC design dictates the use of a CCD-based system for reading out the signals from the scintillating fiber bundle. However, we will be closely monitoring technology developments that may offer significant advantages in the readout of a SONTRAC device. Readout schemes based on the use of multi-anode PMTs, hybrid PMTs or on avalanche photodiode arrays (APDs) may become viable options within the next few years.

The operation of a SONTRAC device represents the accumulation of large volumes of (imaging) data. For remote operations, much of the processing should take place on-board to reduce telemetry and/or data recording requirements. The science model study represents an opportunity to investigate data processing issues important in future engineering and flight model detectors. We will develop and evaluate data processing algorithms for (three-dimensional) event recognition, track recognition, data compression and track reconstruction that could be employed in future instrumentation.
7. CONCLUSIONS

This technique works! The signal to noise ratio is at least four times higher than required. There is sufficient signal even in the more demanding applications where detection of the tracks of minimum ionizing particles is required. Event-by-event detection and measurement of track length (energy), track direction and particle type has been accomplished. Specifically, we have fabricated a small SONTRAC prototype and demonstrated a self-triggered detector system for ionization track imaging of individual events. This has been done for minimum ionizing cosmic ray muons, the recoil protons from incident 14 MeV to 65 MeV neutrons and for incident 20 MeV to 65 MeV protons. We have demonstrated SONTRAC’s neutron detection, spectroscopic and imaging capabilities from the threshold necessary for the solar physics study. We have explored and developed useful calibration and data analysis techniques using proton beams and in the process we have demonstrated imaging capabilities directly applicable to other fields. We have developed a preliminary response model and demonstrated agreement with the laboratory measurements. As a result of this effort key engineering parameters such as photoelectron yield, achievable energy threshold, scintillating fiber composition, fiber pitch, EMA requirements, photocathode and phosphor selection have been determined allowing us now to extend these techniques to larger detectors for higher energies with the ability to track in three dimensions.
