Abstract. We report on the POLAR/CEPPAD discovery of a trapped, 60°<θ<120° pitch angle electron population in the outer cusp (7-9+ Re), whose energetic electron component extends from below 30 keV to ~2 MeV. Because the time variability in the outer cusp precludes mapping with POLAR, we have carried out test particle simulations using the Tsyganenko 1996 model (T96) to demonstrate the trapping of these energy electrons in the outer cusp region and the resonant frequencies of its trapped motion. We discuss the boundaries and regions of the cusp trap and show that it is analogous to the dipole trap. We show that the phase space densities observed there are equal or greater than the phase space densities observed in the radiation belts at constant magnetic moment, thus allowing the possibility of diffusive filling of the radiation belts from the cusp.

Introduction

The Earth's magnetosphere has the important topological property of a magnetic bottle, field lines that have stronger magnetic field strength at the ends than in the middle, thereby permitting the trapping of plasma via the mirror force and the azimuthal symmetry of vertical stripes in the upper panels are an instrument artifact caused by mode switching of the HIST telescope. Successive panels are logarithmically spaced in energy where each panel displays the roll modulation (pitch angle) of the particles. The inset plots the count rates of selected energy bands linearly scaled from 0-20 cts/s as a function of pitch angle averaged over the interval 0100-0330 UT. The color scale displays the logarithm of f (s^-3/km^2) from 0.00001 (purple) to 100 (red). From 0100-0315 UT the plot shows 30-1000 keV electrons with trapped pitch angle distributions located in the outer cusp at L> 10. After 0330 UT is an outer radiation belt traversal. Comparing the radiation belt and cusp loss cones, we see that the cusp's is much wider (FWHM=90°), which is characteristic of a "leaky magnetic bottle". It also appears that the wide loss cone of the cusp is filled at a lower, isotropic level. Comparing the phase space densities at equal magnetic moment (black dots at a constant 7.4 keV/nT), reveals that the outer cusp may have equal or higher phase space densities at 90° than the outer radiation belts. However these two regions of high phase space density are bracketed in L-shell by regions of lower density: the polar cap UT<0130, the pseudo-trapping region of the outer zone, 0315<UT<0345, and the slot region separating the outer and inner zones at UT>0500.
Simulations

Now this trapped cusp population is highly unusual because, classically speaking, the cusp cannot trap particles \cite{Roederer1970}; it is not an "excluded region" in the Störmer theory of an ideal dipole \cite{Störmer1911, Rossi and Olbert1970}. However, the interaction of a magnetic dipole with the solar wind modifies the topology in a fundamental way; rather than a dipole, the cusp appears to be quadrupolar. We demonstrate the existence of this particle trap using the geomagnetic conditions of a nearly minimum latitude cusp and a nominal 11 Re standoff distance (Figure 2).

When we trace particles through this region we find trapping to occur when the electrons mirror around the local minimum of the field line found at the center of the cusp. The orbits take the shape of a lily, with a locally outward magnetic gradient instead of the typical inward gradient so that the particles drift 360° around the cusp in an opposite sense to the trapped radiation belt particles. Our results show that 5–6000 keV electrons can be trapped in the cusp of a T96 magnetosphere for \( \tau > 300 \) seconds (i.e., many drift orbits), though admittedly without an electric field. Examination of particle trajectories in this region shows that although they lack a dipolar 2nd and 3rd invariant, since they never cross the dipole magnetic equator, we can find an analogous 2nd and 3rd "cusp" invariants of the motion if we define the "cusp equator" to be the surface of minimum |\( B_0 \)| along field lines that approach the cusp. Thus we can uniquely identify these invariants in analogy to a dipole by their pitch angle and |\( B_0 \)| at the crossing of the cusp equator. In Figure 2 one can see three nested "cusp-shells" analogous to L-shells of the dipole. The limiting 2nd invariant of these trapped orbits occurs when the mirror point |\( B_m \)| approaches the dayside equatorial field strength, at which point the electrons join the dipolar pseudo-trapped population and \( \nabla B \)-drift away from the cusp. From the pitch angle distribution, this value appears to be \( \alpha_0 \sim 60° \). The spatial limit on the 3rd invariant is the maximum value of |\( B_0 \)| for which the "cusp equator" is still defined over a closed, 360° loop.

Can these particles have come from the tail, that is, are they topologically connected to the nightside trapped particles that have drifted into the bifurcated dayside minimum? Yes, they are physically in the same region of space but separated in phase space by very different 2nd invariants principally because the cusp |\( B_0 \)| minima are deeper than the corresponding tail minimum. Take for example a 50 keV 90° pitch-angle particle in the outer cusp, mirroring at 25 nT. For it to maintain the same magnetic moment while drifting, it must find a region of the magnetosphere with \( \sim 25 \) nT fields. The only other such region is deep in the tail, and topologically disconnected from the cusp, so that the particles remain trapped in the cusp and cannot drift away without destroying their first and second invariant. Conversely a 50 keV 90° pitch-angle particle trapped at midnight in a 50 nT field can mirror through the cusp, but its pitch-angle when at the 25 nT level must be 30°. Thus the faint background level inside the wide cusp loss cones could be understood as dipole-trapped particles, but if the first two invariants remain conserved, the peak at 90° can only be locally trapped.

Why was this region not predicted previously? Just as Störmer theory, developed for an azimuthally symmetric dipole field, was recognised to predict trapping only after the discovery of the Van Allen belts, so

**Figure 1.** Electrons trapped in the cusp observed by POLAR/CEPPAD. See text for details.
this broken symmetry of a quadrupole cusp was recognized to predict trapping only after the observation of trapped cusp energetic particles [Chen et al.(1997)]. It is true that the existence of a cusp third invariant was speculated to partially explain the observation of 450 keV electrons [Antonova and Shabanskiy(1975); Shabansky(1971)], but these orbits were never calculated, and indeed, the observed trapped particles were identified with the 2nd invariant "branching" of a drifting dipole-trapped plasma. That is, the off-equatorial $|E_0|$ minimum and the resulting dayside bifurcation of drift orbits has been known since the Beard-Mead model [Mead and Beard(1964)], but the separate existence of a closed, non-bifurcated drift orbit around the cusp had not been previously demonstrated. Previous efforts at particle tracing in the cusp followed less energetic particles whose trajectories are dominated by electric field convection rather than $\nabla B$-drift, and therefore not trapped in the cusp [Delcourt et al.(1992)].

Recognizing that the cusp possesses three adiabatic invariants of the motion, we can characterize the trapped plasma in the cusp by direct analogy to the well-known dipole trap. High energy plasma is dominated by $\nabla B$-drift whose closed drift paths form an annulus analogous to radiation belts. Low energy plasma is dominated by $E \times B$-drift, which because of the lack of an analogous corotation field, distorts the drift orbits and sweeps away plasma below some threshold energy, $\lesssim 30$ keV. The finite size of the cusp produces energy- and mass-dependent inner and outer spatial limits on trapping, analogous to the inner and outer edge of the radiation belts. Finally, the limits on the strength of the mirror force arising from topological considerations produce analogous pitch angle loss cones. Unlike the dipole trap, in which the loss cone loses particles to atmospheric scattering and charge exchange, the cusp loss cone loses particles to the dipolar magnetosphere or the mantle, so in one sense, the cusp trap is half-embedded within the dipole trap.

All these analogies are true for a static magnetic cusp geometry, but are strongly modified by time variable fields, with occasions when $\Delta B/B \gtrsim 1$ [Chen et al.(1998)]. The dipole trap, by comparison, is extremely stable, with $\Delta B/B \ll 1$ over the majority of the trap volume. A second difference with far reaching effects is the separation of the periods of motion.

Figure 2. Trajectories of trapped 1 MeV electrons in the the Earth's outer cusp, projected into the GSM X-Z and Y-Z planes. Dashed lines are field lines from the T96 magnetic field model (Dipole: June 21, 1996, 1300UT; Solar Wind: $+10nT \ B_z$, $1/cm^2$, and $1000km/s \ V_{sw}$). Black lines are contours of $|B|$ in nT. Green, blue and red trajectories correspond to the 1,3,4 entries of Table 1.
The dipole trap has roughly three orders of magnitude separating the gyration, bounce and drift timescales \cite{Lyons and Williams1984}, whereas in the cusp trap these motions may be separated by less than an order of magnitude (See Table 1). Since the conservation of the adiabatic invariants depends upon the separation of timescales, the cusp trap is expected to be much more diffusive in energy and space than the dipole trap. This greater inherent diffusivity, coupled with the large perturbative power available would make the cusp an ideal location for resonance-broadened, chaotic acceleration \cite{Arnold1964}.

Discussion and Conclusions

We have shown that the POLAR spacecraft observed trapped MeV electrons in the Earth's cusp, and that these distributions are consistent with particles trapped in the outer cusp simulated using the Tsyganenko 96 model. Although this trapping geometry is quite different than the standard dipole geometry, we show that an analogous three invariants of the motion exist for this trapped population as well. The peak in the observed phase space density at the location of the outer cusp suggests both that the particles are being accelerated \textit{in situ} and that they are a potential source population for diffusion into the dipole radiation belts. If so, this would provide a neat solution to the puzzle of the origin of the outer radiation belt electrons. However, diffusion in pitch-angle as well as in L-shell would be required to transport these particles from the outer cusp to the radiation belts, since the radiation belt pass is at a higher magnetic latitude which maps the trapped flux into the wide loss cones of the outer cusp. Furthermore, the minima between these trapping regions at 0330 UT indicates that any transport between them is either taking a circuitous route or is necessarily time-dependent. In a later paper we present the result of a time-dependent radial diffusion model of the outer radiation belt.
